Featured Application: The results provide a useful guideline for manipulation of novel vector structure beams by using twist phases and customized correlation functions, and promote important potential applications, ranging from beam shaping, optical tweezers, optical imaging, and free space optical communications.

Abstract: Recently, partially coherent beams with twist phases have attracted growing interest due to their nontrivial dynamic characteristics. In this work, the propagation characteristics of a twisted cosine-Gaussian correlated radially polarized beam such as the spectral intensity, the spectral degree of coherence, the state of polarization, and the spectral change are investigated in detail. Due to the presence of the twisted phase, the beam spot, the degree of coherence, and the state of polarization experience rotation during transmission, but the degree of polarization is not twisted. Meanwhile, although their rotation speeds closely depend on the value of the twist factor, they all undergo a rotation of $\pi/2$ when they reach the focal plane. Furthermore, the effect of the twist phase on the spectral change is similar to the coherence, which is achieved by modulating the spectral density distribution during transmission. The twist phase opens up a useful guideline for manipulation of novel vector structure beams and enriches potential applications in the field of beam shaping, optical tweezers, optical imaging, and free space optical communications.

Keywords: partially coherent; radially polarized; twist phase; state of polarization

1. Introduction

It is well-known that the coherence properties play an important role in determining the spatial behaviors of light beams under propagation [1–10]. For instance, there is a Fourier reciprocal relationship between the initial coherence and the far field intensity distribution [1,2]. Also, it has been proven that the source coherence can apparently influence the evolution behaviors of the degree of polarization and state of polarization of light beams after propagation, even in free space [7,8]. These results contradict the common belief that polarization is propagation invariant. However, most of the studies concerning the spatial coherence sources are restricted to the so-called Schell-model (SM) correlations, where the spectral degree of coherences obey Gaussian distributions [1–3]. In recent years, based on the nonnegative definiteness criteria of the cross-spectral density (CSD), Gori and Santarsiero proposed a sufficient condition for devising genuine correlation functions and quickly extended to the vector cases [11,12]. Manipulation of nontrivial correlation structures to produce
prescribed structure beams with tailored intensity, polarization, and phase, and to explore novel spatial behaviors has seen a rapid growth of interest due to their important applications in optical imaging, optical tweezers, free-space optical communications, laser radar, and remote sensing [13–33].

In previous decades, much prominence has been given to radially polarized beams because of their nontrivial properties and potential applications such as lithography, display technologies, optical trapping, optical data storage, and confocal microscopy [34–42]. A partially coherent radially polarized beam was introduced as a natural extension of a coherent cylindrical vector beam. Paraxial and non-paraxial properties of partially coherent radially polarized beams have been investigated in detail [43–49]. Statistical properties of partially coherent radially polarized beams in random media such as a turbulent atmosphere and ocean turbulence have been studied [50,51]. It is demonstrated that partially coherent radially polarized beams are more effective at resisting signal distortion caused by turbulence than general linearly polarized partially coherent beams. Moreover, by manipulating the correlation structures of source beams, the ability to generate tunable partially coherent radially polarized array beams was demonstrated [22–26].

In 1993, Simon and Mukunda proposed that a partially coherent beam has the ability to carry a new type of phase-twist phase, and this was later generated experimentally by Friberg et al. [52,53]. Recently, on the basis of the nonnegative constraint of the CSD, Gori et al. introduced a new method to design twisted sources endowed with circular or rectangular symmetry [54,55]. Due to the existence of the twist phase, twisted partially coherent beams not only have the ability to carry orbital angular momentum, but also have better anti-turbulence self-repairing capabilities, which can find applications in optical tweezers, optical imaging, and optical communications [56–64]. Besides, owing to their nontrivial angular momentum mechanical properties, twisted partially coherent beams are receiving increasing attention [65,66]. In this paper, our aim is to study the focusing properties of a new class of partially coherent radially polarized beams with a nontrivial cosine-Gaussian correlation function and a twisted phase. The effects of the twist phase on the spectral intensity, the spectral degree of coherence, the degree of polarization, the state of polarization, and the spectral change are investigated in detail. The results yield a useful guideline for manipulation of novel vector structure beams by using twist phases and customized correlation functions, and promote important potential applications, ranging from beam shaping, optical tweezers, optical imaging, and free space optical communications.

2. Theory

It is known that the vector electric field of a radially polarized beam can be described as the coherent superposition of TEM$_{01}$ Laguerre–Gaussian modes oriented along the $x$ axis and a TEM$_{10}$ oriented along the $y$ axis at $z = 0$ [43–48].

$$ E(r) = E_x(r)e_x + E_y(r)e_y = \frac{x}{w_0} \exp\left(\frac{-r^2}{w_0^2}\right)e_x + \frac{y}{w_0} \exp\left(\frac{-r^2}{w_0^2}\right)e_y, $$

where $r = (x^2 + y^2)^{1/2}$ denotes the transversal distance from the beam center and $w_0$ is the transverse beam size. For a vector partially coherent beam in space-frequency domain, the second-order correlation properties of a fluctuating light beam can be completely described by the CSD matrix $W(r_1, r_2)$ with elements $W(r_1, r_2) = \langle E^*_\alpha(r_1)E_\beta(r_2) \rangle$, $\alpha, \beta \in \{x, y\}$. $r_1$ and $r_2$ denote two arbitrary points with position vectors in the source plane. For brevity, we omit the explicit dependence of the considered quantities on frequency $\omega$. The asterisk denotes the complex conjugate and the angular brackets represent average over the statistical ensemble. For a partially coherent radially polarized beam, the elements of the CSD matrix are described as [46]:

$$ W_{\alpha\beta}(r_1, r_2) = \frac{\alpha_1^2\beta_2^2}{w_0^2} \exp\left(\frac{-r_1^2 + r_2^2}{w_0^2}\right)g_{\alpha\beta}(r_1, r_2), \quad (\alpha, \beta \in \{x, y\}), $$

where $g_{\alpha\beta}(r_1, r_2)$ is the correlation function.
where $g$ denotes the degree of coherence.

It is important to note that the coherence structure is independent of spectral density profile. So, one can independently modulate the coherence function without affecting the spectral density of random sources [54]. Here, let us consider the coherence function of the initial beam to have a twisted cosine-Gaussian correlated (CGC) function [25,54]:

$$s_{\alpha\beta}(r_1, r_2) = \exp \left[-\frac{(r_1 - r_2)^2}{2\sigma_0^2}\right] \cos \left[\frac{n\sqrt{\pi}(y_1 - y_2)}{\sigma_0}\right] \cos \left[\frac{n\sqrt{\pi}(x_1 - x_2)}{\sigma_0}\right] \exp[-ik\mu(x_1y_2 - x_2y_1)],$$  

(3)

where $\delta_0$ denotes coherence parameter, $n$ is a positive beam order parameter, and $\mu$ represents the twist phase. When $n = 0$, a twisted CGC radially polarized beam reduces to a conventional Schell-model (SM) radially polarized beam [44–48]. Using Mercer’s expansion, it is proven that the realizability condition for generation of such twisted random source coincides with SM sources. As a new class of twisted non-uniformly correlated vector beams, a possible experimental approach for generating twisted CGC radially polarized beams can be achieved by using a spatial light modulator and an astigmatic optical lens system [20,25,53]. In [25], we have demonstrated an experiment for generating a CGC correlated radially polarized beam. One may further produce a twisted CGC radially polarized beam by passing a CGC correlated radially polarized beam through an astigmatic optical lens system [53].

Within the framework of paraxial approximation, the elements of the CSD matrix of a twisted CGC radially polarized beam through an ABCD optical system can be written as [2]:

$$W_{\alpha\beta}(r_1, r_2') = \frac{k_0^2}{4\pi^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} s_{\alpha\beta}(k, r_1) s_{\alpha\beta}(k', r_2') \exp \left[-\frac{i}{2\pi k} (r_1 - r_2') \right] \exp \left[\frac{i}{2\pi k} (A r_1^2 - 2r_1 \cdot r_2' + D r_2'^2) \right] \, d^2 r_1 d^2 r_2'.

$$

(4)

On substituting Equations (2) and (3) into Equation (4), after some algebra the elements of the CSD matrix of a twisted CGC radially polarized beam in the output plane turn out to be:

$$W_{xx}(r_1, r_2') = \frac{k_0^2}{64\pi^2 \beta N_2 N_2' (N_2 - \Omega)^2} \exp \left[\frac{-ikD}{2\pi} (r_1^2 - r_2'^2) \right] \times \sum_{a_1 = \pm a} \sum_{a_2 = \pm a} \xi_{u11} (\xi_{u21} + i\Pi_1) \delta_0^{-2} - \frac{(\xi_{u21} - \Pi_1)^2}{2\delta_0^2 (N_2 - \Omega)^2} - k\mu (\xi_{u21} + i\Pi_1) (\xi_{u22} - \Omega_2) \frac{(\xi_{u22} - \Omega_2)^2}{2\delta_0^2 (N_2 - \Omega)^2}

$$

(5)

$$W_{yy}(r_1, r_2') = \frac{k_0^2}{64\pi^2 \beta N_2 N_2' (N_2 - \Omega)^2} \exp \left[\frac{-ikD}{2\pi} (r_1^2 - r_2'^2) \right] \times \sum_{a_1 = \pm a} \sum_{a_2 = \pm a} \xi_{v12} (\xi_{v22} + i\Pi_2) \delta_0^{-2} - \frac{(\xi_{v22} - \Omega_2)^2}{2\delta_0^2 (N_2 - \Omega)^2} - k\mu (\xi_{v22} + i\Pi_2) (\xi_{v21} - \Omega_1) \frac{(\xi_{v22} - \Omega_2)^2}{2\delta_0^2 (N_2 - \Omega)^2}

$$

(6)

$$W_{xy}(r_1, r_2') = \frac{k_0^2}{64\pi^2 \beta N_2 N_2' (N_2 - \Omega)^2} \exp \left[\frac{-ikD}{2\pi} (r_1^2 - r_2'^2) \right] \times \sum_{a_1 = \pm a} \sum_{a_2 = \pm a} \xi_{u11} (\xi_{v22} + i\Pi_2) \delta_0^{-2} - \frac{(\xi_{v22} - \Omega_2)^2}{2\delta_0^2 (N_2 - \Omega)^2} - k\mu (\xi_{v22} + i\Pi_2) (\xi_{v21} - \Omega_1) \frac{(\xi_{v22} - \Omega_2)^2}{2\delta_0^2 (N_2 - \Omega)^2}

$$

(7)

where

$$a = \sqrt{2\pi n}/\delta_0, \quad N_1 = \frac{1}{4\pi^2} + \frac{i\alpha}{4\sigma_0^2}, \quad N_2 = \frac{1}{4\pi^2} - \frac{1}{4\sigma_0^2} - \frac{i\mu}{2\sigma_0^2},

\xi_{u11} = k\xi_{u11}' / B + a_1, \quad \xi_{u21} = k\xi_{u21}' / B + a_1, \quad \xi_{v12} = k\xi_{v12}' / B + a_2, \quad \xi_{v22} = k\xi_{v22}' / B + a_2,

\Omega = \frac{1}{4N_0\sigma_0^2} - \frac{k_0^2}{4\pi^2}, \quad \Pi_1 = \frac{\xi_{u11} B}{2N_0\sigma_0^2} - \frac{\xi_{u21} B}{2N_0\sigma_0^2} - \frac{\xi_{v12} B}{2N_0\sigma_0^2} + \frac{\xi_{v22} B}{2N_0\sigma_0^2}.

$$

(8)
On the basis of the CSD matrix of an electromagnetic beam, there are three important fundamental statistical characteristics that can be defined as:

the spectral density

$$S(r') = W_{xx}(r', r') + W_{yy}(r', r'),$$  \hspace{1cm} (9)

the spectral degree of coherence (DOC)

$$\eta(r'_1, r'_2) = \frac{\text{Tr}[W(r'_1, r'_2)]}{\left(\text{Tr}[W(r'_1, r'_1)]\text{Tr}[W(r'_2, r'_2)]\right)^{1/2}},$$  \hspace{1cm} (10)

and the degree of polarization (DOP)

$$P(r') = \left(1 - \frac{4\text{Det}[W(r', r')]}{(\text{Tr}[W(r', r')])^2}\right)^{1/2}. \hspace{1cm} (11)$$

In Equations (9)–(11), Tr represents the trace and Det denotes the determinant. It should be noted that there is another definition of the spectral DOC for electromagnetic beams introduced by Tervo et al., which is also widely used [9].

### 3. Numerical Results

Now, we numerically analyze the focusing properties of a twisted CGC radially polarized beam with the help of the theoretical results derived above. Let us consider the source beam passes through a thin lens with focal length $f$ and then arrives at the receiver plane. The ray matrix of such optical system reads as:

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} 1 & z \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ -1/f & 1 \end{pmatrix}\begin{pmatrix} 1 & f \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 - z/f & f \\ -1/f & 0 \end{pmatrix}. \hspace{1cm} (12)$$

The global parameters used in the following calculations are set as $\lambda = 632.8 \text{ nm}$, $w_0 = 1 \text{ mm}$, $\delta_0 = 0.2 \text{ mm}$, $\mu = 0.001 \text{ mm}^{-1}$, and $f = 150 \text{ mm}$, unless different values are specified. In Figure 1, we depict the normalized spectral density distribution and the corresponding cross line of a twisted CGC radially polarized beam focused by a thin lens at several propagation distances for different values of $n$. For the case of $n \neq 0$, it is shown that the spectral density gradually decomposes into a four-beamlets array distribution, and the distance between each beamlet grows as the beam order $n$ increases. Moreover, one clearly sees that the spectral density distribution of a twisted CGC radially polarized beam in the focal plane is significantly different from that in the absence of the twist phase. As expected, for a CGC radially polarized beam without the twist phase, there is a Fourier-like relation between the spectral density in the focal plane and the initial correlation function [25]. However, for a twisted CGC radially polarized beam, this genuine reciprocal relationship disappears due to the existence of the twist phase, see Figure 1a3,b3,c3. The reason for this is that the twist phase leads to a beam astigmatism during diffraction, which causes a focal shift.
In order to study the spectral density distribution of polarization components $W_{xx}(r, r')$ and $W_{yy}(r', r)$, Figure 2 plots the normalized polarized spectral density components and the corresponding cross lines at several propagation distances with $n = 2$. It is clearly seen that the spectral density not only splits during spreading, but also each spectral density component undergoes a rotation of $\pi/2$ within the focal length. In addition, for a CGC radially polarized beam, see Figure 2b4,c4, one finds that the two orthogonal spectral density components have the same distribution in the focal plane.

Figure 3 shows the modulus of the spectral DOC and the corresponding cross line at different propagating distances for different values of $n$. One finds that the array structure of the spectral DOC becomes more complex with the growth of the order parameter $n$. Similar to the spectral density, it is clearly seen that the spectral DOC rotates during the spreading and also experience a rotation of $\pi/2$ when they reach the focal plane. At the same time, it is found that the rotation speed depends only on the twist phase, see Figure 3b1–b3,c1–c3. In addition, due to the existence of the twist phase, the Fourier reciprocal relationship between the spectral DOC in the focal plane and the initial spectral intensity no longer exists. Thus, the spectral DOC of a twisted CGC radially polarized beam in the focal plane is quite different from that without the twist phase [25].
Figure 2. Normalized spectral intensity distribution, polarized spectral intensity components $W_{xx}(r, r')$ and $W_{yy}(r, r')$, and the corresponding cross line of a focused twisted CGC radially polarized beam at different propagating distances with $n = 2$. For (a1–a4), (b1–b4), (c1–c3) $\mu = 0.001 \text{mm}^{-1}$; (a5,b5,c5) $\mu = 0 \text{mm}^{-1}$.

Figure 3. Modulus of the spectral degree of coherence (DOC) and the corresponding cross line of a focused twisted CGC radially polarized beam at different propagation distances for different values of $n$. For (a1–a4), (b1–b4), (c1–c4) $\mu = 0.001 \text{mm}^{-1}$; (a5,b5,c5) $\mu = 0 \text{mm}^{-1}$.

Figure 4 illustrates the effect of the twist phase on the spectral DOC. As is seen from Figure 4, the rotation speed is nonlinear and closely depends on the value of the twist factor. However, when they reach the focal plane, they all undergo a rotation of $\pi/2$, regardless of the value of the twist phase. Furthermore, it is of interest to see that the spectral DOC spot becomes larger as the twist factor increases due to the beam divergence caused by the twist phase.
In addition, quite different from the spectral density and the spectral DOC, a striking feature can be seen in which the twist phase does not lead to a rotation of the DOP. However, for a twisted SM radially polarized beam, it is interesting to see from Figure 5a1–a3 that a similar on-axis DOP singularity disappears due to the existence of a twisted phase. It has been shown that the on-axis DOP singularity of an SM radially polarized beam is propagation invariant [51].

Figure 4. Modulus of the spectral DOC and the corresponding cross line of focused twisted CGC radially polarized beam at different propagation distances for different values of the twist phase. For (a1–a4) $\mu = 0.0005 \text{mm}^{-1}$; (b1–b4) $\mu = 0.001 \text{mm}^{-1}$; (c1–c4) $\mu = 0.002 \text{mm}^{-1}$; (a5,b5,c5) $\mu = 0 \text{mm}^{-1}$.

In order to learn more about the vector properties, in Figure 5 the behaviors of the DOP of a focused twisted CGC radially polarized beam at different propagation distances for different values of $n$ is plotted. It has been shown that the on-axis DOP singularity of an SM radially polarized beam is propagation invariant [51]. However, for a twisted SM radially polarized beam, it is interesting to see from Figure 5a1–a3 that a similar on-axis DOP singularity disappears due to the existence of a twisted phase. In addition, quite different from the spectral density and the spectral DOC, a striking feature can be seen in which the twist phase does not lead to a rotation of the DOP.

Figure 6 illustrates the DOP and the corresponding cross line of a focused twisted CGC radially polarized beam at different propagation distances for different values of the twist phase. It is seen that the complex DOP structure gradually degenerates and becomes more uniform. This is because the astigmatism gradually increases with the increase of twist factor.

Figure 5. Density plot of the DOP and the corresponding cross line of a focused twisted CGC radially polarized beam at different propagation distances for different values of $n$. For (a1–a3), (b1–b3), (c1–c3) $\mu = 0.001 \text{mm}^{-1}$; (a4,b4,c4) $\mu = 0 \text{mm}^{-1}$.
Next, let us further evaluate the effects of the twist phase on the state of polarization (SOP). It is well known that the CSD matrix can be represented as a sum of a completely polarized beam and a completely unpolarized beam [2]. For a partially coherent beam, the polarization ellipse is a parameter characterizing the fully polarized portion of the beam. By using the CSD matrix, one can conveniently determine the polarization ellipse, including the major and minor semiaxes of the polarization ellipse, and the orientation angle [8]. The orientation angle $\varphi$ is given by the following formula:

$$\varphi(r',r) = \frac{1}{2} \arctan \left( \frac{2\text{Re}[W_{xy}(r',r)]}{W_{xx}(r,r') - W_{yy}(r,r')} \right), \quad (-\pi/2 \leq \varphi \leq \pi/2),$$  

(13)

and the major and minor semiaxes of the polarization ellipse take the following form:

$$A_{\pm}(r',r) = \frac{1}{2} \left\{ \sqrt{(W_{xx} - W_{yy})^2 + 4|W_{xy}|^2} \pm \sqrt{(W_{xx} - W_{yy})^2 + 4(\text{Re}[W_{xy}])^2} \right\}^{1/2}.$$

(14)

Then, the degree of ellipticity $\varepsilon$ characterizing the shape of the polarization ellipse of an electromagnetic beam is defined by:

$$\varepsilon = A_-(r',r')/A_+(r,r'), \quad 0 \leq \varepsilon \leq 1.$$  

(15)

On submitting from Equations (5)–(8) into Equations (13)–(15), we numerically investigated the behaviors of the SOP in Figure 7 of a focused twisted CGC radially polarized beam at different propagation distances for different values of the twist phase. Owing to the twisted phase, it is of interest to find from Figure 7a1–a4 that the initial radially polarized structure gradually evolves into an azimuthally polarized structure in the focal plane. Moreover, similar to the spectral DOC, one finds that the SOP experiences a rotation of $\pi/2$ with the focal length, regardless of the value of order $n$. In addition,
for the case of \( n \neq 0 \), the SOP splits with the splitting of the spectral intensity, which is the same as that in absence of the twist phase [25,26].

Figure 8 shows the dependence of the SOP on the twist phase. Similar to the spectral density and the spectral DOC, it is seen that although the twist speed of the SOP closely depends on the value of the twist phase, the SOP always rotates \( \pi/2 \) within the focal length compared to that without twist factor. Therefore, it is worthwhile to manipulate novel complex vector beams by taking advantage of the twist phase and tailored coherence structure.

**Figure 7.** The state of polarization (SOP) and the corresponding cross line of a focused twisted CGC radially polarized beam at different propagation distances for different values of \( n \). For (a1–a3), (b1–b3), (c1–c3) \( \mu = 0.001 \text{ mm}^{-1} \); (a4,b4,c4) \( \mu = 0 \text{ mm}^{-1} \).

**Figure 8.** The SOP and the corresponding cross line of focused twisted CGC radially polarized beam at different propagation distances for different values of the twist phase with \( 2n = \). For (a1–a4) \( \mu = 0.0005 \text{ mm}^{-1} \); (b1–b4) \( \mu = 0.001 \text{ mm}^{-1} \); (c1–c4) \( \mu = 0.002 \text{ mm}^{-1} \).
Finally, we concentrate our attention on the spectral properties of a focused polychromatic twisted CGC radially polarized beam. It is well known that the correlation-induced spectral change (also called the “Wolf effect”) is an important feature of partially coherent beams. It was demonstrated that Wolf effect has important applications in optical signal processing, information encoding and exchange [5,6,67–70]. Since the spectral change is closely related to the coherence and polarization, it is meaningful to study the spectral shift of a twisted nontrivial CGC radially polarized beam. Here, let us assume that the initial spectrum is a Lorentz type with ω0 being the central frequency and Γ0 being the half-width at half-maximum, and ω is the angular frequency. Then the elements of the CSD matrix of a focused polychromatic twisted CGC radially polarized beam in the output plane are given as:

\[
W_{xx}(r_1, r_2, \omega) = \frac{k^2}{64\omega_0^6 B^2 N_0^2 (N_2 - \Omega)^2} \cdot \frac{\Gamma_0^2}{(\omega - \omega_0)^2 + \Gamma_0^2} \exp \left[ -\frac{i k \Omega}{2 B} (r_1^2 - r_2^2) \right] \\
\times \sum_{d_1 = \pm 1} \sum_{d_2 = \pm 1} \left[ \xi_{111} (\xi_{220} + i \Pi_1) + \delta_0 - \frac{(i \nu_{220} - \Pi_1)^2}{2 \Delta_0 (N_2 - \Omega)} + \frac{k \eta (\xi_{222} + \Pi_1) (\xi_{220} - \Pi_1)}{4 (N_2 - \Omega)} \right] \\
\times \exp \left[ -\frac{\upsilon_{211} + \upsilon_{211}}{4 N_1} + \frac{(i \nu_{222} - \Pi_1)^2 + (i \nu_{220} - \Pi_1)^2}{4 (N_2 - \Omega)} \right].
\]

(16)

\[
W_{yy}(r_1, r_2, \omega) = \frac{k^2}{64\omega_0^6 B^2 N_0^2 (N_2 - \Omega)^2} \cdot \frac{\Gamma_0^2}{(\omega - \omega_0)^2 + \Gamma_0^2} \exp \left[ -\frac{i k \Omega}{2 B} (r_1^2 - r_2^2) \right] \\
\times \sum_{d_1 = \pm 1} \sum_{d_2 = \pm 1} \left[ \xi_{111} (\xi_{222} + i \Pi_1) + \delta_0^2 - \frac{(i \nu_{222} - \Pi_1)^2}{2 \Delta_0 (N_2 - \Omega)} - \frac{k \eta (\xi_{222} + \Pi_1) (\xi_{220} - \Pi_1)}{2 (N_2 - \Omega)} \right] \\
\times \exp \left[ -\frac{\upsilon_{211} + \upsilon_{211}}{4 N_1} + \frac{(i \nu_{222} - \Pi_1)^2 + (i \nu_{220} - \Pi_1)^2}{4 (N_2 - \Omega)} \right].
\]

(17)

\[
W_{xy}(r_1, r_2, \omega) = \frac{k^2}{64\omega_0^6 B^2 N_0^2 (N_2 - \Omega)^2} \cdot \frac{\Gamma_0^2}{(\omega - \omega_0)^2 + \Gamma_0^2} \exp \left[ -\frac{i k \Omega}{2 B} (r_1^2 - r_2^2) \right] \\
\times \sum_{d_1 = \pm 1} \sum_{d_2 = \pm 1} \left[ \xi_{111} (\xi_{222} + i \Pi_2) + i k \mu + i k \mu \right] \\
\times \exp \left[ -\frac{\upsilon_{211} + \upsilon_{211}}{4 N_1} + \frac{(i \nu_{222} - \Pi_1)^2 + (i \nu_{220} - \Pi_1)^2}{4 (N_2 - \Omega)} \right].
\]

(18)

Now, we numerically investigate the relative spectral changes of a polychromatic twisted CGC radially polarized beam focused by a thin lens. The spectral shift Δω is the difference between the peak frequency ω_\text{max} of the spectrum after propagation and the central frequency ω_0 of the source spectrum. A positive value of Δω means a blueshift, while a negative value denotes a redshift. The relative spectral shift can be defined as:

\[
\gamma = (\omega_{\text{max}} - \omega_0) / \omega_0.
\]

(19)

The parameters are set as ω_0 = 3.6 × 10^{15} and Γ_0 = 1 × 10^{14}. Figure 9 shows the relative spectral shift γ of a focused polychromatic twisted CGC radially polarized beam versus the propagation distance z. For a polychromatic partially coherent radially polarized beam without the twist phase, a study showed that an on-axis blueshift can be found before and after the focus [47]. However, for a polychromatic twisted radially polarized beam, the on-axis spectral shift is always redshifted, with the minimum redshift occurring in the focal plane, see Figure 9e. With the increase of the beam order n, the blueshift appears and the maximum blueshift occurs in the focal plane. In addition, one also finds that the maximum redshift occurs off-axis in the focal plane and grows rapidly as the off-axis distance y increases. In order to learn more about the effect of the twist phase on spectral shift, Figure 9b–d plots the relative spectral shift of a focused polychromatic twisted CGC radially polarized beam versus the propagation distance for different values of the twist phase. One finds that the maximum value of redshift and blueshift are significantly reduced as the twist phase increases. The direct reason is that the divergence of the beam increases with the growth of the twist phase. As a result, the spectral density distribution becomes more uniform, leading to a gradual decrease in the difference in spectral shift. This is similar to the correlation-induced spectral change [2,5]. Moreover, different from a polychromatic radially polarized SM beam [47], one finds from Figure 9f that there is
a bimodal blueshift observed near the focal plane for a polychromatic CGC radially polarized beam with \( n = 1 \). It is important to note that the effect of the twist phase on the spectral change is similar to the coherence, which is achieved by modulating the spectral density distribution upon propagation.

**Figure 9.** Relative spectral shift \( \gamma \) of a focused polychromatic twisted CGC radially polarized beam versus the propagation distance and the ordinate \( y \) with \( x = 0 \), and relative on-axis spectral shift versus the propagation distance. For (a–d) contour plots of the relative spectral shift with \( x = 0 \); (e,f) on-axis relative spectral shift with \( x = 0, y = 0 \).

### 4. Conclusions

As a summary, we have studied the focusing properties of a new class of twisted cosine-Gaussian correlated radially polarized beam. It is shown that the twist phase leads to an astigmatism of the light beam, thereby affecting the various statistical properties of the beam during spreading. Because of the twisted phase, the beam spot, the degree of coherence, and the state of polarization experience rotation during transmission, but the degree of polarization is not twisted. Meanwhile, although the rotation speed is nonlinear and closely depends on the value of the twist factor, they all undergo a rotation of \( \pi/2 \) when they reach the focal plane. In addition, it turns out that the effect of the twist phase on the spectral change is essentially similar to coherence, which is achieved by modulating the spectral density distribution during transmission. These results provide a useful guideline for the adjustable twist phase to generate novel partially coherent vector beams and promote important potential applications in the field of beam shaping, optical tweezers, optical imaging, and free space optical communications.
