Abstract: The potential antibacterial activity of basil (Ocimum basilicum), chamomile (Matricaria chamomilla), origanum (Thymus capitatus), tea tree (Melaleuca alternifolia) and thyme (Thymus vulgaris) essential oils, was investigated against 29 Gram-positive bacterial strains isolated from wastewater treatment plants, clinical samples (n = 25) and American Type Culture Collection (ATCC) reference strains (n = 4). Wild bacterial strains included methicillin-resistant Staphylococcus aureus (n = 16) and vancomycin-resistant Enterococcus spp. (n = 9). The antimicrobial activity of the selected oils was studied using the broth macrodilution method. The Minimal Inhibitory Concentration (MIC) values for S. aureus ranged from 0.06 to 0.5% (v/v) for origanum oil, 0.06 to 1% (v/v) for thyme oil, 0.12 to 1% (v/v) for tea tree oil, 0.25 to 4% (v/v) for basil oil and 2 to >4% (v/v) for chamomile oil. For enterococci the MIC values were significantly higher ranging from 0.25 to 1% (v/v), 0.5 to 2% (v/v), 1 to 4% (v/v), 4 to >4% (v/v) and >4% (v/v) for the above-mentioned oils, respectively. The main compounds of the tested essential oils were: estragole (Ocimum basilicum), bisabolol and trans-b-farnesene (Matricaria chamomilla), carvacrol and thymol (Thymus capitatus), terpinen-4-ol and p-cymene (Melaleuca alternifolia), thymol, linalool, and p-cymene (Thymus vulgaris). Origanum essential oil yielded the best antimicrobial results followed by thyme, tea tree, and basil oil, while chamomile oil exhibited weak antibacterial properties.

Keywords: essential oils; antimicrobial activity; MIC; multi-drug resistant; MRSA; VRE

1. Introduction

Medicinal plants have been used, since the Hippocrates era, for healing a wide range of diseases including infectious, systematic and inflammatory diseases [1,2]. In contrast the current antimicrobial drugs are used for the treatment of human and animal infections for just less than a century now [3–5].
In addition, the development of drug-resistant pathogens appeared quickly, while the emergence of multi-drug resistant strains has increased exponentially during the recent years [6].

Methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), *Streptococcus pneumoniae*, *Mycobacterium tuberculosis*, *Enterobacteriaceae* producing extended spectrum b-lactamases (ESBLs) and carbapenemases, multidrug-resistant isolates causing severe hospital infections in immunocompromised individuals such as *Pseudomonas aeruginosa* and *Acinetobacter baumannii* are increasingly reported from both the human and veterinary medicine practice and the aquatic environment as well [4,7–14].

With the emergence of drug resistance and the shortage of effective therapeutics to treat infectious diseases, medicinal plants attracted the attention of researchers looking for new compounds with potent antimicrobial activity. Recent studies suggest plant-essential oils to be associated with sufficient antimicrobial properties against several foodborne pathogens, indicating good prospective for use in food preservation [15–21]. Moreover, there are published data on their use in farm animals for prophylaxis from infectious diseases and as safer substitutes for the antibiotics used for growth promotion [22–26].

Among the actions targeting to reduce and solve the drug-resistance problem is the search for novel antibiotic substances; hence essential oils and their compounds appear to be encouraging replacements. However, most of the published research in this field concerns either reference bacterial strains or non-pathogenic bacteria. Even though there are a few papers concerning clinical isolates [27–31], there is limited information on the essential oils’ effect on drug-resistant strains [32–35]. The goal of the present study was to explore the antibacterial effectiveness against multi-drug resistant Gram-positive bacteria isolated from waste water treatment plants and clinical specimens, of five essential oils, which though being widely used in previously conducted studies, their effectiveness against drug-resistant strains is barely addressed in the relevant bibliography.

2. Materials and Methods

2.1. Microorganisms

The bacterial strains used in this study were isolates from clinical specimens and hospital raw sewage samples obtained from the strain collection of the Microbiology Department (University of Ioannina, Ioannina, Greece). The clinical isolates were: MRSA (n = 16, seven isolates from wound swabs, one isolate from blood culture and eight isolates from hospital raw sewage samples) and VRE (n = 9, two *E. faecium* isolates from wound swabs and seven *E. faecalis* isolates from hospital raw sewage samples). The strains from the American Type Culture Collection were *S. aureus* ATCC 29213, *S. aureus* ATCC 43300, *S. epidermidis* ATCC 12228, and *E. faecalis* ATCC 51299.

The isolation of the clinical strains used in the present study was performed according to the routine procedures employed by the Clinical Microbiology Laboratory of the University Hospital of Ioannina. Blood specimen were inoculated directly into Bact/Alert® disposable culture bottles, and incubated in the Bact/Alert® Microbial Detection System (bioMerieux SA, Marcy l’Etoile, France). Wound swabs were cultured in Blood agar, Mannitol salt agar and Bile esculin agar (Oxoid Ltd., Basingstoke, UK) and were incubated at 37 °C for 24–48 h. VITEK®2 microbial ID/AST testing system (bioMerieux SA, Marcy l’Etoile, France) provided identification and susceptibility results. Raw sewage samples were concentrated using the filtration technique onto 0.45-µm pore size filter membranes (Merck, Darmstadt, Germany) and placed onto the surface of Mannitol salt agar and Bile esculin media, (Oxoid Ltd., Basingstoke, UK). The plates were incubated aerobically for 48 h at 37 °C. The identification of isolated species was determined using the API Staph and API 20 STREP identification systems (bioMerieux SA, Marcy l’Etoile, France). The susceptibility tests were carried out using the agar diffusion method and E-test (bioMerieux SA, Marcy l’Etoile, France) following the Clinical and Laboratory Standards Institute (CLSI) guidelines [36]. Susceptibility to the following antibiotics was
tested: ampicillin, cefoxitin, ciprofloxacin, clindamycin, erythromycin, gentamicin, linezolid, penicillin G, quinupristin/dalfopristin, teicoplanin, tetracycline and vancomycin.

2.2. Essential Oils

The following five essential oils were supplied by Sigma-Aldrich Co (Germany): Basil oil (FCC, comoric type, W211907, Ocimum basilicum L., Lamiaceae), Chamomile blue oil (W227307, Matricaria chamomilla L., Asteraceae), Origanum oil (FCC, W282812, Thymus capitatus L., Labiatae), Tea tree oil (W390208, Melaleuca alternifolia, Myrtaceae), Thyme oil-white (FCC, Kosher, W306509, Thymus vulgaris L., Lamiaceae). Since the supplier provided no data about the chemical analysis of these essential oils, a Gas Chromatography—Mass Spectrometry method (GC/MS-QP5000 Shimadzu, Kyoto, Japan) was used as previously reported [35]. Chromatographic conditions and major identified components of the studied essential oils are shown in Table 1.

2.3. Microbiological Assays

Broth macrodilution assays were performed to determine the Minimal Inhibitory Concentration (MIC) and the Minimal Bactericidal Concentration (MBC) for the essential oils according to the CLSI protocol [36] with minor modifications as previously described [35]. Two-fold serial dilutions of each oil were prepared in Mueller-Hinton broth (MHB, Oxoid Ltd., Basingstoke, UK), with a concentration range of 4% (v/v) to 0.016% (v/v). Tween 20 (Thermo Fisher Scientific, Waltham, MA, USA) was used as a solubilizer at a concentration of 0.5% (v/v). Bacterial inoculum measured by DEN-1 densitometer (Grant Ltd., Cambridgeshire, UK) at a turbidity of 0.5 McFarland (1–1.5 × 10^8 cfu/mL), was transferred into MHB to obtain a bacterial count of 5 × 10^5 cfu/mL. After a 24 h incubation at 37 °C aerobically, an appropriate amount of 10 µL was plated onto Mueller-Hinton agar (MHA, Oxoid Ltd., Basingstoke, UK) and incubated under the aforementioned conditions. Viable counts method was used for determination of MIC and MBC values. The MIC is defined as the lowest concentration of an antimicrobial agent that prevents visible growth of a microorganism in an agar or broth dilution susceptibility test. The MBC is identified by determining the lowest concentration of antibacterial agent that reduces the viability of the initial bacterial inoculum by a pre-determined reduction such as ≥99.9% [37–39].

Time-kill kinetics were performed by exposing the tested microorganisms to the two-fold serial concentrations of each essential oil, ranging from 0.063% to 4% (v/v) and assessed by viable counts procedure [39]. At 0, 1, 3, 6, 8, 12, 24 and 48 h of the dilutions’ incubation, 10-µL amount of each tube was plated onto duplicate plates of MHA and after 24 h of incubation at 37 °C, plates were checked for
visible bacterial growth. Experiments were performed in triplicate and viable counts (cfu/mL) plotted in logarithmic phase in relation to time.

2.4. Statistical Analysis

SPSS Statistics V22.0 was used for statistical analysis (IBM Corp., Armonk, NY, USA).

3. Results

The antimicrobial susceptibility of the tested isolates is presented in Table 2. Both MRSA and VRE were identified as multidrug-resistant (resistance to 3 or more antibiotics classes tested).

Table 2. Antimicrobial resistance (%) of the strains used in this study.

MIC values of selected essential oils against MRSA, VRE and ATCC strains are presented in Figure 1. Origanum, thyme, tea tree and basil oils demonstrated antibacterial activity, while MIC values were higher on the wild MRSA isolates than on the reference strains S. aureus ATCC 29213, S. aureus ATCC 43300 and S. epidermidis ATCC 12228 as well. In general, chamomile oil demonstrated no antibacterial action. The only exception was one sensitive MRSA strain in which both low bacteriostatic (MIC = 2% v/v) and bactericidal (MBC = 2% v/v) efficacy was occurred (Figure 1A). Origanum, thyme, and tea tree oils demonstrated great antimicrobial activity against enterococci, while basil and chamomile oils presented weak and no antimicrobial properties, respectively (Figure 1B). The range of MIC and MBC values of the tested essential oils against the selected isolates are presented in Table 3. The mean values of the MICs ± SD (% v/v) reported for MRSA were 0.25 ± 0.14 for origanum oil, 0.41 ± 0.27 for thyme oil, 0.56 ± 0.30 for tea tree oil, and 1.42 ± 1.43 for basil oil. Regarding enterococci, origanum oil demonstrated the most significant antimicrobial activity (0.58 ± 0.28), followed by thyme oil (1.22 ± 0.60) and tea tree oil (2 ± 1.22).
In Figures 2 and 3 the time-kill assays of each essential oil at concentrations ranging from 0.125% up to 4% (v/v) against two of the tested clinical isolates (one VRE and one MRSA) are presented. In these two assays, in contrast to the majority of the tested bacteria, the presented VRE isolate (VRE no. 2) exhibited bactericidal response to tea tree and thyme oils at 1% (v/v) and 0.5% (v/v) concentrations respectively at 48 h, while the total reduction of viable cells was achieved at higher concentrations at 24 h (Figure 2). However, the activity of the afore-mentioned oils was reduced at 48 h on three clinical MRSA isolates and the bactericidal values were one dilution higher than the displayed values at 24 h. Figure 3 presents an example of one clinical MRSA strain (MRSA no. 4) isolated from wound swab, which demonstrated bactericidal response at 1% (v/v) and 2% (v/v) to tea tree oil and at 0.12% (v/v) and 0.25% (v/v) to thyme oil, after 24 h and 48 h of incubation, respectively.
Figure 1. Comparison of MIC values of selected essential oils against wild and ATCC staphylococci (Α), wild and ATCC enterococci (Β).

In Figures 2 and 3 the time-kill assays of each essential oil at concentrations ranging from 0.125% up to 4% (v/v) against two of the tested clinical isolates (one VRE and one MRSA) are presented. In these two example assays, in contrast to the majority of the tested bacteria, the presented VRE isolate (VRE no. 2) exhibited bactericidal response to tea tree and thyme oils at 1% (v/v) and 0.5% (v/v) concentrations respectively at 48 h, while the total reduction of viable cells was achieved at higher concentrations at 24 h (Figure 2). However, the activity of the aforementioned oils was reduced at 48 h on three clinical MRSA isolates and the bactericidal values were one dilution higher than the displayed values at 24 h. Figure 3 presents an example of one clinical MRSA strain (MRSA no. 4) isolated from wound swab, which demonstrated bactericidal response at 1% (v/v) and 2% (v/v) to tea tree oil and at 0.12% (v/v) and 0.25% (v/v) to thyme oil, after 24 h and 48 h of incubation, respectively.

Figure 2. Time-kill kinetics for origanum oil, basil oil, tea tree oil, and thyme oil on a vancomycin resistant E. faecium (VRE no. 2) clinical isolate (isolated from wound swab).

Figure 3. Time-kill kinetics for origanum oil, basil oil, tea tree oil, and thyme oil on the MRSA no. 4 clinical isolate (isolated from wound swab).

4. Discussion

The emergence of resistant bacteria is of imperative significance for public health safety [40]. The observed evolution of drug resistance is the end-result of long term selective pressure applied to...
bacteria due to inconsiderate exploitation of the drug use. The appearance of drug-resistance leads to
decrease of the existing therapeutic options thus implying the urgency for the development of new
antimicrobials [35]. For centuries it has been well acknowledged the potential of medicinal plants to
produce a wide range of phytochemicals, mostly alkaloids, phenolic compounds, polyacetylenes
and polypeptides [2,35,41]. In particular, essential oils have been studied for antimicrobial
properties against various non-pathogenic microorganisms and to a lesser extent against pathogenic
microorganisms. Although their activity against bacteria of the same genera and species appears to be
comparable, yet drug-resistant clinical isolates may show different response from the usually used
reference strains [42,43]. Therefore, to better document the antimicrobial performance of essential oils,
it is essential to test drug-resistant isolates from different sources (diseased humans, animals, food,
water, environment) in order to have a realistic indication of their antimicrobial effect [35]. In the
available literature the majority of the published papers employ reference strains, or non-pathogenic
strains and scarcely multi-drug resistant isolates. This variety in the used strains and the diversity of
the employed methods produces variable findings and the comparative assessment of the published
results is difficult.

Regarding the essential oils and the bacterial isolates employed in the present study the literature
search revealed only a few publications relating to drug-resistant clinical strains. However, there
are variations in the methodological approach that make any comparison of their findings with
our results rather inaccurate. A study on the antimicrobial activity of origanum (Origanum vulgare)
and basil (Ocimum basilicum) oils against clinical strains of S. aureus showed that only origanum
essential oil was effective and concluded that wild clinical strains are less sensitive to essential oils
compared to prototype strains but no data on the strain susceptibility are presented [29]. Nostro et al.
(2004) using the agar diffusion method, have evaluated the MIC values of origanum oil (O. vulgare,
thymol chemotype) at a range of 0.063 to 0.125% (v/v) against methicillin-resistant S. aureus and
methicillin-resistant S. epidermidis strains and at 0.125% (v/v) against S. aureus ATCC 25923, S. aureus
ATCC 43300 and S. epidermidis ATCC 12228 [44]. Although Nostro et al., have used the same ATCC
strains which we used in our study too, the methodological approach is different justifying the
observed discrepancies (Table 3). Preuss et al. (2005) report that the MIC of S. aureus ATCC 33591 to
origanum oil, determined by a broth microdilution method, was 0.5% (v/v), but here again this is a
different reference strain [45]. Hammer et al. (1999), using the broth microdilution method, evaluated
the MIC of tea tree oil, basil oil, origanum oil, and thyme oil against S. aureus National Collection of
Type Cultures (NCTC) 6571 at concentrations 0.5%, 2%, 0.12% and 0.25% (v/v) respectively [46], while
Carson et al. (2002) report that the MIC and MBC of tea tree oil against S. aureus ATCC 9144 were
determined at concentrations 0.25% and 0.5% (v/v) respectively [47], but a different reference strain
was used and no clinical drug-resistant isolates were tested. Mann and Markham (1997) using the
broth microdilution method, report the MIC for tea tree oil against MRSA at concentration of 0.08%
(v/v), which was less than that in our study, however the findings cannot be compared because no
data from the sensitivity tests are provided [48]. Hammer et al. (1996) report the tea tree oil MIC and
MBC against S. aureus to be 0.12–0.5% (v/v) and 0.25–2% (v/v) respectively [37], whereas Nelson (2000)
reports that the tea tree oil MIC against MRSA was 0.25% (v/v) without providing the sensitivity test
details [49]. Both studies, presented similar results with our findings (Table 3), but again there are
differences in the methodological approaches.

In the present study the MIC values reported for origanum oil, thyme oil and tea tree oil against
S. aureus (MRSA, reference strains) in general are not different from those reported by other researchers,
but still there is the methodological diversity difference. Concerning the reported MIC values for
basil oil in our study they were much different denoting much less effective antimicrobial activity
against drug-resistant clinical isolates. In the aforementioned literature the methods used for the
determination of the antimicrobial activity of the essential oils, included agar well diffusion assays,
paper disk diffusion assays, agar dilution assays and broth microdilution and macrodilution methods.
Even surfactants such as Tween 20 (polyoxyethylene 2-sorbitan monolaurate) or Tween 80 (polysorbate
are variable in different papers, even though they are used only to enhance oil solubility without contributing to the antimicrobial activity. Regarding the employed essential oils, even when identical names are reported it is uncertain whether their main constituents are exactly the same. Several factors such as the plant growth stage, environmental and ecological conditions, harvesting and processing conditions, and plant endogenous factors can affect the composition of the extracted essential oil [39].

Nevertheless, our results like most of the findings reported by other researchers indicate that essential oils are likely to act as alternative antimicrobial agents against some multi-drug resistant Gram-positive isolates. It has to be emphasized that Gram-positive bacteria are not considered to be as resistant as the Gram-negatives [50]. To a large extent this trait is attributed to differences in their cell wall structure which is less complex in Gram-positives than in Gram-negatives, allowing the penetration of antimicrobial compounds, such as the phenolic compounds (e.g., thymol, carvacrol, eugenol) of the essential oils [18,51]. The cell wall of the Gram-positive bacteria permits hydrophobic molecules to get into the cells and act on the cell wall and the cytoplasm. Apparently, the potential antimicrobial activity of the essential oils’ compounds derives from their ability to disrupt the bacterial cell wall and the cytoplasmic membrane, consequently leading to cell lysis and leakage of intracellular compounds [52]. Taking into consideration that an intact cell wall is vital for the bacterium survival, any changes in the permeability of the cell wall and cytoplasmic membrane affect the bacterial propagation. In the presence of antibacterial compounds in their environment, bacteria are forced to alter the synthesis of fatty acids and membrane proteins in order to survive by modifying the permeability of their cell wall [53,54]. Essential oils particularly those rich in phenolics have the ability to penetrate the phospholipids layer of the bacterial cell wall, bind to proteins and block their functions. Existing data on the essential oils antimicrobial activity show that their potency depends on several biochemical and structural mechanisms that take place at various sites of the bacterial cell and more research in this direction is needed to explore thoroughly the antimicrobial potential of plant essential oils.
