Abstract: Hexagonal perovskite YFeO$_3$ was synthesized by a complex-assisted sol-gel technique allowing crystallization at calcination temperatures below 700 °C. As determined by diffuse reflectance spectroscopy (DRS) and Tauc plots, the hexagonal YFeO$_3$ exhibits a lower optical band gap (1.81 eV) than the orthorhombic structure (about 2.1 eV or even higher) being typically obtained at elevated temperatures (>700 °C), and thus enables higher visible light photocatalysis activity. Structure and morphology of the synthesized YFeO$_3$ perovskites were analyzed by powder X-ray diffraction (XRD) and nitrogen adsorption, proving that significantly smaller crystallite sizes and higher surface areas are obtained for YFeO$_3$ with a hexagonal phase. The photocatalytic activity of the different YFeO$_3$ phases was deduced via the degradation of the model pollutants methyl orange and 4-chlorophenol. Experiments under illumination with light of different wavelengths, in the presence of different trapping elements, as well as photoelectrochemical tests allow conclusions regarding band positions of YFeO$_3$ and the photocatalytic degradation mechanism. X-ray photoelectron spectroscopy indicates that a very thin layer of Y$_2$O$_3$ might support the photocatalysis by improving the separation of photogenerated charge carriers.

Keywords: vis-light photocatalyst; hexagonal YFeO$_3$; methyl orange degradation; Mott-Schottky plot; X-ray photoelectron spectroscopy

1. Introduction

Visible light photocatalysis is a well-known technique for the purification of environmental contaminations [1–3]. Many studies were carried out in the last few years in order to develop new compounds with narrow band gaps to increase the visible light response of photocatalysts [4,5]. Due to their high chemical stability, oxides are the most attractive class of compounds; the use of mixed metal oxides allows for an effective tailoring of the physicochemical properties. Oxides with perovskite structure are of special interest, since they show some important features with respect to catalysis, optics, and magnetism [6,7]. The fact that the perovskite structure is highly flexible allows more than 90% of the metallic elements in the periodic table to be stable in this structure. This lead to a wide variety of compositions with varying $A:B$ ratios which deviate from the expected ideal $ABO_3$. Such compositional variations are accompanied by the formation of cation and oxygen vacancies which control the transport, adsorption, and optical properties of the material [8]. Even after consideration of the Goldschmidt tolerance factor (an empirical indicator for the stability of crystal structures of perovskites, $ABO_3$) [9], a wide variation of the cations on the $A$ and $B$ positions is possible, allowing a rational design of the band structure, i.e., the band gap as well as the energetic band positions. Perovskites with small band gaps are of special interest; ferrites are one class of them. Review papers summarizing the actual status on photocatalysis with ferrites with respect to hydrogen formation as well as decontamination of water.
have been authored by Dillert et al. and Sharma et al. [10,11]. The photoelectrochemical behavior and theoretical investigations related to solar water splitting was also summarized recently by Taffa et al. [12]. Yttrium ferrite is a magnetic material which is of practical advantage since it can be simply recovered from catalysis suspensions by use of external magnets [13,14]. Besides its magnetic and magneto-optical properties, YFeO$_3$ is also used in environmental monitoring applications such as sensors, anode material for batteries, lasers, and catalysis [15].

YFeO$_3$ exhibits a narrow band gap rendering it interesting for photocatalysis [16,17]. It was shown that the photocatalytic properties strongly depend on the particle size which is influenced by the chosen preparation method [1,4,18]. However, despite its advantages, the numbers of studies done on YFeO$_3$ are still limited because quite challenging synthesis methods [19] such as a KCl-assisted solution combustion synthesis (SSCS) [16] or microwave-assisted methods are required [1]. Most of the current approaches for synthesis of single phase perovskite YFeO$_3$ require a calcination process at a high temperature causing a growth of large particles. Furthermore, according to the phase diagram, the structure of YFeO$_3$ is thermodynamically quite unstable and converts easily to more stable compounds like Y$_3$Fe$_5$O$_{12}$ or Fe$_2$O$_3$, this hampers, for example, the microwave-assisted method [1,13]. In order to prevent particle agglomeration and sintering, different fuels and adjustment of fuel-to-oxidant molar ratios were chosen in the combustion process of ferrites, however, in many cases, more nanophases rather than individual nano-sized particles were obtained [20]. Therefore, controlled synthesis of ferrite and especially YFeO$_3$ nanoparticles with defined crystal structure is still an experimental challenge.

Sol-gel technique is in general a very effective method to synthesize nanomaterials at low temperatures, leading to higher purity and improved homogeneity of the prepared compounds [21]. Quite often in photocatalytic studies of YFeO$_3$, orthorhombic or hexagonal structures are reported to be present together [22,23]. However, Zhang et al. reported a citric acid assisted sol-gel method to synthesize pure hexagonal and orthorhombic YFeO$_3$ displaying low surface areas (<5 m$^2$/g). Their photoactivities were tested towards the degradation of methyl orange using a 400 W halogen lamp and a 420 nm cut-off filter [18]. In this study, we applied the same synthesis route, but altered temperature and duration of the thermal treatment. We found that the pyrolysis step is crucial to obtain hexagonal YFeO$_3$ with high surface area (ca. 25 m$^2$/g). Similar to Zhang et al., the degradation of methyl orange was used for the investigation of the photocatalytic activities with visible light, but we also extended the tests to 4-chlorophenol (4-CP) as a colorless organic pollutant not absorbing in the visible light range. Thus, it proves that direct excitation of the photocatalyst YFeO$_3$ by the applied light with wavelengths of 420 nm and higher is responsible for the photodegradation. Additionally, the main reactive oxygen species are identified and photoelectrochemical data are presented to support the enhanced visible activity of hexagonal over orthorhombic YFeO$_3$.

2. Results and Discussion

2.1. Structural, Optical, and Electrochemical Characterization of Hexagonal YFeO$_3$

The XRD patterns of the synthesized YFeO$_3$ samples calcined at different temperatures are shown in Figure 1. For calcination temperatures of up to 650 °C, no distinct reflexes are observable in the XRD patterns, showing that the samples are amorphous. The broad signal at around 2θ = 30°–35° already indicates the start of the formation of YFeO$_3$ crystallite, but the crystallite size is too small to form well separated reflexes. From the XRD patterns, the formation of the perovskite YFeO$_3$ structure is revealed after post-thermal treatment at 675 °C and 700 °C. All the reflexes are indexed to the hexagonal YFeO$_3$ structure (International Center of Diffraction Data (ICDD)-00-048-0529, 2009). There are no other extra reflexes detected, proving the effective preparation of single phase perovskite YFeO$_3$ without any impurities by the citric acid assisted sol-gel route. By increasing the calcination temperature to 800 or 900 °C, the hexagonal to orthorhombic phase transformation of YFeO$_3$ takes place (ICDD-00-011-0558, 2009). Thus, the structure of YFeO$_3$ can be simply tailored by the calcination temperature; the hexagonal phase is metastable and converts to the thermodynamically more stable...
orthorhombic phase at higher temperature [22]. Previous studies based on the thermal decomposition of yttrium nitrate and iron nitrate reported the same phase transformation, but only mixtures of hexagonal and orthorhombic crystals were obtained at 675 to 750 °C. After further heating to 800 °C, the orthorhombic YFeO$_3$ phase contaminated with impurities of Y$_2$O$_3$ was obtained [24]. In contrast, the sol-gel route applied here leads to pure phases. It is worth mentioning that the stability of the hexagonal phase depends not only on the calcination temperatures but also on the particle size, metal-to-fuel ratios, and the method of synthesis [25,26].

![Figure 1](image_url). XRD patterns of YFeO$_3$ calcined at different temperatures. The peak positions in reference diffraction patterns of the hexagonal (ICDD-00-048-0529) and orthorhombic (ICDD-00-011-0558) YFeO$_3$ are also indicated by gray and black lines, respectively.

With increasing temperature, the intensity of the XRD reflexes increases and gets sharper, indicating a higher degree of crystallization. By use of the Scherrer equation:

$$\tau = K\lambda / B\cos\theta$$  \hspace{1cm} (1)

where $\tau$ is average crystallite size, $\lambda$ is the X-ray wavelength (nm), $B$ is the peak width at half maxima of the diffraction pattern (in radians) and $K$ is a constant related to crystallite shape generally taken as 0.9, the crystallite size of 14.7 nm is observed for sample hex-675 with hexagonal structure and 46.8 nm for sample orth-900 with orthorhombic structure. The reflexes with the highest intensity at around $2\theta = 33^\circ$ were selected for calculating the crystallite size of both samples. Furthermore, the SEM micrographs (Figure S1a,b) show small domain sizes for the hex-675 sample and the domain sizes increase for the orth-900 sample due to thermal sintering of the particles. Additionally, the energy-dispersive X-ray spectroscopy (EDXS) analysis (Figure S1c) show the presence of Fe:Y with a ratio of almost 1:1, and the O amount is slightly higher than the stoichiometric values.

Surface areas were determined from N$_2$ adsorption-desorption isotherms. Classical type IV isotherms with a H3 hysteresis loop were obtained for hex-675 and hex-700, reflecting the presence of a mesoporous material (Figure 2). According to International Union of Pure and Applied Chemistry (IUPAC) reports, this kind of hysteresis is exhibited by non-rigid aggregates of plate-like particles or incomplete pore filling of a network consisting of macropores [27]. For orth-800 and orth-900, the adsorption was much lower, reflecting low surface area solid material with type Ia isotherms (Figure 2). The applied complex-assisted sol-gel synthesis route and the low calcination temperature of 675 °C lead to a high surface area (24.7 m$^2$/g), exceeding data reported from other studies (11.7 m$^2$/g$^{-1}$) [1]. With increasing calcination temperature, the surface area decreases continuously, reaching a value of 5.6 m$^2$/g for YFeO$_3$ calcined at 900 °C (orth-900). This agrees with the increase
of the crystallite sizes as estimated from the Scherrer equation. The form of the isotherms indicates that mostly mesoporous interparticle voids are present. Furthermore, the steep increases at very low partial pressures for hex-675 and hex-700 resulting from the filling of micropores with diameters of a maximum of 1 nm might not only result from voids of the 15 nm small crystallites in the hexagonal phase, but might additionally indicate the presence of some structural micropores in the crystallites.

![Figure 2](image2.png)

**Figure 2.** N$_2$ adsorption isotherms for Brunauer-Emmett-Teller (BET) surface area determination of YFeO$_3$ calcined at the indicated temperatures.

To estimate the optical properties of the YFeO$_3$ synthesized at different calcination temperatures, their visible light absorption spectra were studied by measuring the diffuse reflectance mode and are shown in Figure 3a. YFeO$_3$ with the hexagonal phase (hex-675 and orth-700) clearly exhibits absorption edges closer to 700 nm, enabling the use of a higher fraction of the solar visible light spectrum for photocatalysis.

![Figure 3](image3.png)

**Figure 3.** (a) Kubelka-Munk function (F(R)) vs. wavelength, showing the absorption onsets. The insets show the colors of the YFeO$_3$ powders (b) Tauc plots for indirect band gap determination of the YFeO$_3$ samples.

In Figure 3b the Tauc plots obtained from the absorption data by plotting of $(F(R)\times h\nu)^{1/2}$ versus the photon energy ($h\nu$) are shown, where $F(R)$ is the Kubelka-Munk function. The band gap energies $E_{\text{gap}}$ obtained from the intercepts with the energy axis [28] show a difference of about 0.3 eV for the hexagonal and the orthorhombic YFeO$_3$ phase. With respect to the band gap of Fe$_2$O$_3$ of 2.1 eV, the introduction of yttrium ions leading to the hexagonal perovskite phase causes a shift of the band gap to a lower energy. For YFeO$_3$ prepared by a microwave-assisted approach, a band gap of 2.43 eV was reported [1]; for nanocrystalline YFeO$_3$ prepared via a hydrothermal route and subsequent calcination at 800 °C, a band gap of 2.37 eV was found [29]. These higher values are caused by the presence of the orthorhombic...
phase or a mixture of hexagonal and orthorhombic phases, and agree roughly with our findings for the pure orthorhombic phase.

The surface composition and the chemical states of Fe and Y in both hexagonal (hex-675) and orthorhombic (orth-900) YFeO₃ samples were investigated by X-ray photoelectron spectroscopy (XPS). Figure 4a shows the high resolution Y 3d region with two spin-orbit doublets with the main peaks located at binding energies of 156.3 and 158.3 eV for hex-675 and at 156.8 and 158.8 eV for orth-900, respectively. In general, the reported Y 3d5/2 peak position varies between 156 and 157 eV and the measured binding energies at 156.3 and 156.8 eV are in good agreement with reported values for Y₂O₃ [30,31]. The Y 3d peak can further be resolved into minor doublets at 157.4 and 159.4 eV and 157.8 and 160.0 eV for hex-675 and orth-900, respectively. They are assigned to the underlying YFeO₃, and the Y 3d5/2 peak positions at 157.4 and 157.8 are close to the reported values. [32] A shift to higher binding energy (0.4 eV) for the orthorhombic phase may arise from the high coordination of Y with O compared to lower coordination in the hexagonal phase. In Figure 4b, the main O1s photoelectron lines at 529.13 and 529.27 eV are assigned to the lattice oxygen in hexagonal (hex-675) and orthorhombic (orth-900) YFeO₃, respectively [33]. The broad peak centered at 531.3 eV is assigned to surface O due to hydroxides species or origination from the Y₂O₃ top layer [27]. From Figure 4c, the Fe 2p consists of Fe 2p3/2 and Fe 2p1/2 doublets and satellite features due to spin orbit coupling. The Fe 2p3/2 peak positions at 710.13 and 710. 26 eV show the presence of Fe3+ species in both hex-675 and orth-900 samples, respectively [22]. Additionally, for the orth-900 sample, the intensity loss and shift of the satellite feature to lower binding energy may indicate the presence of Fe2+ or low coordinated Fe in the orthorhombic YFeO₃. The surface composition was calculated using the integrated peak areas under the Fe 3p and Y 3s peaks and showed a slight excess of Y consistent with the presence of a thin Y₂O₃ top layer (Table 1). It is noteworthy to mention that Y₂O₃ as a wide band gap material (E_g = 5.5–5.7 eV) [34,35] is not involved in the light absorption process, however, such thin insulating metal oxides, including Y₂O₃, are commonly used to passivate surface electron traps on various semiconductor surfaces and might lead to enhanced charge carrier separation [36,37]. Hence, the presence of a thin Y₂O₃ layer may be beneficial for the photocatalysis process (see below).

In order to gain further insights into the effect of thermal annealing and the accompanied phase transformation on the photoactivity of YFeO₃ samples, photoelectrochemical studies were performed on doctor-bladed YFeO₃ films by Mott-Schottky (MS) analysis, chopped light voltammetry (CLV), and electrochemical impedance spectroscopy (EIS). According to MS analysis [38] donor densities (ND)
and the flat band potential \( (E_{fb}) \) of planar semiconductor electrodes can be obtained by measuring the frequency dependent space charge capacitance employing Equation (2).

\[
\frac{1}{C^2} = \left[ \frac{2}{\varepsilon_0 \varepsilon \varepsilon_0 N} \right] \left[ E - E_{fb} - \frac{kT}{e} \right]
\]  

(2)

\( C \) is the capacitance of the space charge layer, \( \varepsilon_0 \) the vacuum permittivity, \( \varepsilon \) the dielectric constant of the semiconductor, \( e \) the elementary charge, \( E_{fb} \) the flat band potential, \( T \) the temperature, and \( k \) the Boltzmann constant.

In Figure 5a,b, MS plots for both types of YFeO\(_3\) samples (hex-675 and orth-900) show a positive slope indicating that the hexagonal as well as the orthorhombic YFeO\(_3\) are n-type semiconductors. However, due to surface states and non-uniformity of the films, the two frequencies measured (1 kHz for hex-675 and 5 kHz for orth-900) lead to slightly different intercepts showing deviation from the ideal MS assumption. From the extrapolation to \( 1/C^2 = 0 \), the flat band potential can be estimated, and the obtained values for the hexagonal phase and the orthorhombic phase are 0.4 V and 0.35 V vs. reversible hydrogen electrode (RHE), respectively. For n type semiconductors, the \( E_{fb} \) is close to the bottom of the conduction band (CB); typically it is assumed that CB is 0.1 V more negative than \( E_{fb} \) [39], resulting in CB edges at about 0.3 V and 0.25 V vs. RHE, respectively. These values are significantly different from the negative potential of −0.19 V given for orthorhombic YFeO\(_3\) by Lu et al. [33], which was empirically computed, and explain why YFeO\(_3\) is not able to catalyze light-induced hydrogen formation. The potential of the valence band can be calculated according to the equation \( E_{vb} = E_{cb} + E_{gap} \) [40], resulting in about \( E_{vb} = 2.1 \) V for sample hex-675.

Figure 5. Mott-Schottky plots at 1 kHz and 5 kHz of (a) hex-675, (b) orth-900, (c) chopped light photocurrent measurements in 0.1 M Na\(_2\)SO\(_4\)/0.1 M Na\(_2\)SO\(_3\) solution (pH = 5.6) under white light emitting diode (LED) illumination, and (d) Nyquist plot of hex-675 and orth-900 in 0.1 M Na\(_2\)SO\(_4\) (pH = 5.6) at 0.1 V vs. Ag/AgCl.
For an n-type semiconductor under illumination and potential bias, an anodic photocurrent is expected when the bias is large enough ($E_{bias} > E_{fb}$) to cause sufficient band bending, hence the onset of the photocurrent is closer to the $E_{fb}$ in the presence of a good electron/hole acceptor. In order to cross-check the values obtained from MS, we performed CLV in 0.1 M Na$_2$SO$_4$/0.1 M Na$_2$SO$_3$ solution (Figure 5c). The onsets of the photocurrent lie between 0.4 V and 0.5 V vs. RHE and are, thus, close to the values obtained from MS. Photoelectrochemical impedance spectroscopy (Figure 5d) shows two semi-circles indicating two capacitive time constants related to surface charging/film resistance and a charge transfer process associated to the oxidation of SO$_3^{2-}$. Qualitatively, sample hex-675 shows a lower charge transfer barrier to the oxidation of SO$_3^{2-}$ compared to orth-900. Thus, the hexagonal YFeO$_3$ in hex-675 exhibits better charge transport properties which will enhance the photocativity (see below).

2.2. Photocatalytic Activity of Hexagonal YFeO$_3$

The photocatalytic activities of YFeO$_3$ formed at different temperatures in visible light were evaluated by decomposition of the model organic pollutant methyl orange (MO). Prior to turning on the light for photocatalytic degradation, the adsorption-desorption equilibrium of MO on the YFeO$_3$ surface was established by stirring the photocatalyst/MO mixture in the dark for 40 min. Figure 6a shows the decrease in the absorbance of MO with time of illumination over the hexagonal YFeO$_3$ photocatalyst hex-675. The absorption maximum at 464 nm results from the azo groups (N=N) which are connected to aromatic sp$^2$-hybridized carbon in the MO [41]. The cleavage of this azo group is the first step in the photocatalytic decomposition of MO under illumination.

![Figure 6](image)

**Figure 6.** Photocatalytic degradation tests of methyl orange (MO): (a) The loss of absorbance at 464 nm using hex-675 YFeO$_3$ and (b) comparison of the normalized concentration changes over the different YFeO$_3$ samples and different conditions of illumination for hex-675. Light source: 150 W Xe arc lamp with cut-off filter $\lambda > 420$ nm.

Figure 6b shows the comparison of the photoactivity of different YFeO$_3$ photocatalysts towards the degradation of MO under visible light. Self-degradation (photolysis) was found to be very low under the experimental conditions (MO-blank). In presence of photocatalysts, the degradation efficiency decreased with increasing calcination temperature of YFeO$_3$, reaching 57.5%, 49.3%, 33.1%, and 36.7% after 6 h for hex-675, hex-700, orth-800, and orth-900, respectively.

The results document that the activity of the YFeO$_3$ prepared at low calcination temperature, exhibiting the hexagonal phase, is higher than for that of the orthorhombic phase. Possible reasons are the smaller crystallite sizes, lower band gaps (Figure 3), and higher surface areas (Figure 2). Smaller particle size decreases the probability of recombination of photo-generated charge carriers during transfer from the bulk to the surface of the catalyst. Moreover, the high surface area leads to more substrate adsorption. The narrower band gap energy allows the hexagonal phase to harvest the visible light more efficiently. Additionally, based on the XPS analysis, the higher amount of Y in
orth-900 may lead to a thicker Y₂O₃ coating, which hinders the tunneling of holes, resulting in a higher electron-hole recombination rate [42]. As a result, the order of the photocatalytic activity follows the order hex-675 > hex-700 > orth-800 > orth-900.

As shown in the absorption spectra of MO in Figure 6a, the MO has two absorption maxima located at 464 nm and at 280 nm; this absorption in the UV probably leads to self-excitation or photolysis. The blank curve in Figure 5b rules out that this ultraviolet (UV) absorption leads to a photochemical self-destruction, since in absence of a photocatalyst, the MO concentration remains practically unchanged.

However, a sensitization of the YFeO₃ photocatalyst by the MO might nevertheless be possible; in this case, the excited state of MO might allow electron transfer to the conduction band of YFeO₃ and initiate the degradation process. Thus, a control degradation experiment with pure UV light (λ < 350 nm) was performed. The 280 nm absorption was still excited, but its intensity was by a factor of 3 lower compared to the absorption at 464 nm (Figure 6a). Thus, if sensitization would be an important factor in the degradation process, the photocatalytic activity should decrease. However, Figure 5b shows that for the most active YFeO₃ sample, hex-675, the photocatalytic activity under UV light is enhanced by about 10%. Furthermore, degradation experiments using a bandpass filter (center wavelength at 400 nm, where MO does not absorb) shows degradation activity higher than activity from pure Vis irradiation but lower than activity from pure UV excitation. Thus, sensitization by the MO itself should not be a dominant factor for the degradation; light absorption by yttrium ferrite and subsequent formation of reactive species is much more likely responsible for most of the light-induced MO degradation.

Reactive oxygen species (e.g., -OH, -O₂⁻) are strong oxidizing agents and play a vital role in the photo-assisted degradation of organic contaminants [43,44]. For the photocatalytic degradation of rhodamine B with YFeO₃ under visible light, Chen et al. identified photo-generated holes and hydroxyl radicals as the main active species [15]. However, since the detailed mechanism of the photocatalytic process can vary for different pollutants, further tests were performed in order to identify the reactive species in case of MO degradation. The conversion of terephthalic acid (TA) to a fluorescence active 2-hydroxy terephthalic acid is used to quantify the formation of -OH radicals [45]. In order to check the light induced formation of hydroxyl radicals (-OH), a suspension of an aqueous solution of terephthalic acid and the YFeO₃ photocatalysts was irradiated with visible light (λ > 420 nm). The hydroxyl radical formation was determined by measuring the intensity of the fluorescence maximum of 2-hydroxyterephthalic acid at 425 nm [27]. Very low fluorescence intensity at 426 nm was observed after 4.5 h of irradiation, suggesting slow hydroxyl radical formation (Figure S2). Further tests with different scavenger molecules added to the degradation experiments were performed (Figure 7). Almost no degradation was observed if potassium iodide (10 mM KI) acting as a hole scavenger [46] was added to the photocatalytic reaction mixture. This indicates that direct oxidation by the photogenerated holes is involved in the degradation of MO. Since the oxidation power of the holes formed on the YFeO₃ surface is high, this mechanism is very likely.

![Figure 7](image-url)  
**Figure 7.** Photocatalytic degradation of MO under visible light (λ > 420 nm) over YFeO₃ hex-675 after addition of several trapping reagents in order to identify the active species.
However, with benzoquinone (10 mM BQ), typically acting as a scavenger for superoxide radicals [47], the degradation is strongly reduced (Figure 7). This would imply that the degradation proceeds via superoxide radicals being produced by reaction of adsorbed $O_2$ molecules with excited electrons from the conduction band of the yttrium ferrites. This is, however, quite unlikely for an irradiation with visible light, since their potential is about 0.3 V which is not negative enough to reduce $O_2$ and form superoxide radicals, which requires a potential of $EO_2/O_2^- = -0.046$ V [48]. However, superoxide radicals might be formed by different routes such as illumination with UV light exciting electrons to states at negative potential deep in the conduction band from where a reaction with adsorbed oxygen is possible, excitation via MO molecules, or even via a self-excitation of the benzoquinone. Such excitation of adsorbed aromatic systems was, for example, reported by Neubert et al. [49]. Superoxide radicals ($O_2^-$) would react further with water molecules to hydroxyl radicals. This reaction, however, seems not to take place to a large extent due to very slow formation of the hydroxyl radical in the terephthalic acid test, indicating that involvement of superoxide radicals in the degradation mechanism is not dominant. Thus, the competition of BQ and MO which hampers the MO degradation, might have another reason, probably a blocking of active sites by BQ molecules. With the addition of isopropanol (10% of total volume), a scavenger for hydroxyl radicals [50], only a slight decrease in degradation activity was observed, confirming again that $\cdot$OH radicals are not the dominant active species in the degradation mechanism.

Additionally, in order to further prove the visible photoactivity of these catalysts, the photocatalytic degradation of colorless substrates (e.g., 4-CP) was tested. As shown in Figure S3, 48% of the 4-CP degraded after 5 h of visible light illumination. Other catalytic tests and strategies to improve the photoactivity are currently under study.

3. Materials and Methods

3.1. Materials

All the reagents in this study were commercial products and were used without any purification. The following were purchased from Sigma-Aldrich (Schnelldorf, Germany): iron (III) nitrate nonahydrate (Fe(NO$_3$)$_3$·9H$_2$O (99%)) and citric acid (C$_6$H$_8$O$_7$ (99%)). The following were purchased from Alfa Aesar (Karlsruhe, Germany): yttrium nitrate hexahydrate (Y(NO$_3$)$_3$·6H$_2$O (99.9%)) and methyl orange (C$_{14}$H$_{14}$N$_3$NaO$_3$S, analytical grade). Deionized water (>18 MΩ cm) was obtained from a Sartorius water purification system.

3.2. Synthesis of YFeO$_3$

A modified sol-gel route was used to synthesize hexagonal and/or orthorhombic YFeO$_3$ powders [16]. In a typical synthesis, Fe(NO$_3$)$_3$·9H$_2$O, Y(NO$_3$)$_3$·6H$_2$O, and citric acid were separately dissolved in deionized water under stirring with 1:1:4 molar ratio. Citric acid was used as a complexing agent to chelate metal cations and prevent precipitation, thus, it was needed in surplus. The obtained brown solution was clear and transparent. From the mixture, the gel was obtained by heating at 300 °C for 2-3 h under magnetic stirring. Subsequently, the solvent was evaporated by combustion in a pyrolysis step at 400 °C for 1 h. The resulting fluffy powder was crushed to fine powder and subsequently calcined at different temperatures for 10 h in air. After calcination and cooling, the obtained samples were characterized and tested in the photocatalytic degradation. They were named as amo-650, hex-675, hex-700, orth-800, and orth-900 according to their phase modifications (amorphous, hexagonal, and orthorhombic) and the calcination temperature (in °C) applied.

3.3. Characterization

Powder X-ray diffraction patterns were recorded with a PANalytical X’pert PRO theta-theta X-ray diffraction system (PANalytical, Almelo, The Netherlands) with Cu Kα radiation ($λ = 1.540598$ nm) operating at 40 kV and 40 mA. The UV-vis diffuse reflectance spectra (DRS) and UV-vis absorption
spectra were measured with a VARIAN Cary 4000 (Varian, Mulgrave, Australia) equipped with an integrating sphere. Magnesium oxide (MgO) was used as a white standard and the spectral range was chosen between 200 and 800 nm. The photoluminescence (PL) spectrum was recorded on a VARIAN Cary Eclipse Fluorescence Spectrophotometer (Varian, Mulgrave, Australia). The Brunauer-Emmett-Teller (BET) surface areas were calculated from nitrogen adsorption-desorption isotherms recorded on a Tri Star II or an ASAP 2020 (Micromeretics GmbH, Aachen, Germany). Scanning electron microscopy (HITACHI, S-3200N, Hitachi, Krefeld, Germany) and energy-dispersive X-ray spectroscopy (EDX Oxford INCAx-act, Oxford Instruments, Abingdon, UK) were used to study the sample morphology and the atomic ratio of the sample, respectively. Electrochemical impedance spectroscopy (EIS) and photocurrent measurements were performed using a ZAHNER Zennium potentiostat (Zahner Elektrik GmbH, Kronach, Germany) running under Thales software (version 4.12). A standard three electrode configuration with Ag/AgCl (3 M NaCl), coiled Pt-wire, and YFeO$_3$ coated fluorine-doped tin oxide (FTO) were used as the reference, counter, and working electrodes, respectively. For the preparation of the working electrodes, fluorine-doped tin oxide (FTO) glass slides (Pilkington, Weiherhammer, Germany) with a size of $2 \times 6 \text{ cm}^2$ were cleaned with 0.1 M HCl, 0.1 M NaOH, acetone, and ethanol each for 10 min in an ultrasonic bath. Then, 0.1 g of the respective sample were dispersed in 500 µL ethanol in an ultrasonic bath for 30 min, and 200 µL of the obtained suspension were coated on the FTO glass substrate using doctor blade method. Finally, the FTO substrate was dried in a furnace for 3 h at 600 °C. As electrolyte 0.1 M Na$_2$SO$_4$ or 0.1 M Na$_2$SO$_4$/0.1 M Na$_2$SO$_3$ aqueous solution were used. X-ray photoelectron spectroscopy (XPS) measurements were carried out in an ultra-high vacuum set-up, ESCALAB 250 Xi (Thermo-Fisher, East Grinstead, UK) equipped with a monochromatic Al Kα X-ray source ($h\nu = 1486.6$ eV). The high resolution spectra for the C 1s, O 1s, N 1s, and Fe 2p photoelectron lines were recorded with pass energy of 20 eV and step size of 0.1 eV. The binding energy scales were corrected to the charge shift by referring the most intensive C 1s contribution to 284.8 eV. The spectra were analyzed using Avantage software (version 5.951).

3.4. Photocatalytic Degradation Activity Measurement

Methyl orange (MO) was used as a model organic pollutant for the photocatalytic degradation under visible light irradiation. In a typical test, 0.1 g of YFeO$_3$ was dispersed in 100 mL of $10^{-5}$ M MO aqueous solution under stirring in a water-cooled (10 °C) double wall 250 mL Pyrex glass reactor. The mixture was further stirred for 40 min in the dark to establish the adsorption-desorption equilibrium between the photocatalyst and the MO dye. Then, the samples were illuminated with a 150 W Xe lamp equipped with a 420 nm cut-off filter to have visible light irradiation only. Every hour, a part of the probe was taken out, filtered, and analyzed by UV-vis absorption measurement; the degradation was evaluated from the decrease of the intensity of the absorption maxima of MO at 464 nm.

For the photocatalytic degradation of 4-CP, 0.05 g of the catalyst was suspended in 100 mL of $10^{-4}$ M 4-CP aqueous solution. Then, the experimental procedure and the set-up used were similar to the photodegradation of MO.

4. Conclusions

Pure phase hexagonal YFeO$_3$ was successfully synthesized by the citric acid assisted sol-gel technique and evaluated in photocatalysis. The complexing agents enable the use of moderate calcination temperatures; with that, the hexagonal perovskite structure could be stabilized as a pure phase. As long as calcined at 700 °C or lower, YFeO$_3$ crystallizes in the hexagonal structure; only at higher temperatures the thermodynamically favored orthorhombic structure is formed. With respect to photocatalysis, the formed hexagonal YFeO$_3$ has the advantages of an approximately 0.3 eV smaller optical band gap enabling use of a higher fraction of the visible light, smaller size of the crystallites, and a higher surface area facilitating adsorption of reagents. XPS measurements suggest that the photocatalytic activity might also be enhanced by the presence of a thin film of Y$_2$O$_3$ on the YFeO$_3$ nanoparticles. Mott-Schottky plots and impedance measurements reveal a potential of the CB around
0.3 V, explaining the inactivity for photocatalytic hydrogen evolution. The photocatalytic oxidation reactions to degrade pollutants, as tested with methyl orange and 4-chlorophenol, occur mainly via direct reaction of the photogenerated holes.

**Supplementary Materials:** The following are available online at www.mdpi.com/2073-4344/7/11/326/s1, Figure S1: SEM micrographs of (a) hex-675 and (b) orth-900. (c) The EDXS analysis showing the elemental composition, Figure S2: Fluorescence spectral changes observed during visible light illumination of hex-675 sample in terephthalic acid (TA) solution (3 mM TA/10 mM NaOH M, excitation at 320 nm). The spectra were recorded at intervals of 1.5 h, Figure S3: Photocatalytic degradation curves for 4-CP (1 × 10−3 M) using hex-675. Light source: 150 W Xe arc lamp with cut-off filter λ > 420 nm.
