Abstract: We investigated the influence of the reduction method on the preferential oxidation of CO in H₂ (CO-PROX) over Au/La₂O₃/Al₂O₃ catalysts. An Au/La₂O₃/Al₂O₃ sample, prepared using deposition–precipitation with urea, was reduced by chemical reduction with NaBH₄ or glycerol. Several techniques, such as diffuse-reflectance infrared Fourier-transform spectroscopy after CO adsorption (CO-DRIFTS), X-ray photoelectron spectroscopy (XPS) and transmission electron microscopy (TEM) were used to characterize the catalysts. Additionally, the catalysts were examined by in situ DRIFTS during methanol decomposition. The results reveal that the reduction method affects the average particle size and electronic state of gold, as well as the characteristics of the CO–Au₀ interactions. The best CO-PROX performance was observed for the catalyst chemically reduced using NaBH₄ with a NaBH₄/Au molar ratio of 35. This catalyst contained gold particles with size of ~4 nm, for which the XPS binding energy was lower than that of metallic gold.

Keywords: gold; Au/La₂O₃/Al₂O₃; chemical reduction; NaBH₄; glycerol; CO-PROX; effect of reduction method

1. Introduction

The catalytic removal of CO by preferential CO oxidation in H₂ (CO-PROX) is considered as a promising approach to prepare high-purity H₂ for polymer electrolyte membrane fuel cells [1]. Recent studies have revealed that gold can be an attractive alternative to platinum group metal (PGM)-based catalysts for this process [2], in view of its proven CO oxidation ability at low temperatures and lower catalytic performance in H₂-mediated reactions [3–7]. In particular, the latter property derives from the lower capacity of gold to dissociate hydrogen compared with the PGM catalysts [8–10].

In order to improve the catalytic performance of gold centers in the CO-PROX process, much attention has been focused on the effects of the support and size of the gold particles. Previous investigations of the CO-PROX performance of nanosized gold catalysts supported on Al₂O₃-containing materials revealed that the support plays a more critical role [11–16] than the size of gold particles, because the rates of CO conversion and of undesirable H₂ oxidation increase as the gold particle size decreases and vice versa. The electronic state of gold nanoparticles depends on the nature of the support: slightly electron-deficient (Au⁺) or electron-rich (Au⁻) particles can be generated using acidic and basic oxides, respectively, due to the different charge transfer between the support and the gold particles [17,18]. In the case of Al₂O₃, which possesses both acidic and basic sites, positively and negatively charged metal nanoparticles can be formed [19]. The net charge on the gold nanoparticles can significantly influence the catalytic properties. Since the first report of favorable H₂ dissociation on Au⁰ [20], basic oxide promoters such as lanthanum oxide have been found to be beneficial for the CO-PROX catalytic activity of gold supported on Al₂O₃-based oxides [11,21,22].
In the present study, the deposition–precipitation with urea (DPU) method was adopted to prepare Au/La2O3/Al2O3 catalysts. In general, to obtain supported gold nanoparticles, the as-prepared sample is activated by thermal calcination and/or reduction. The thermal treatment, carried out under H2 flow, results in the formation of smaller gold nanoparticles [23]. However, small gold particles are not favorable for all reactions, especially in the case of selective oxidations. Chemical reduction techniques have been employed to modify the characteristics of gold centers in supported catalysts [24]. The present study focuses on the effect of different reduction methods of the Au/La2O3/Al2O3 catalyst on its CO-PROX activity. The activity of catalysts chemically reduced with aqueous NaBH4 and pure glycerol was compared with that of their H2-reduced counterpart. The effects of the reduction method on the characteristics of the gold catalyst were studied by in situ diffuse-reflectance infrared Fourier-transform spectroscopy (DRIFTS) experiments, in which CO adsorption and methanol decomposition were carried out over the gold catalysts. In addition, transmission electron microscopy (TEM) and X-ray photoelectron spectroscopy (XPS) measurements were performed to inspect the changes in the properties of the gold catalyst according to the reduction method. The observed CO-PROX performance is discussed in light of the analyses mentioned above.

2. Results

2.1. CO-PROX Performance

The CO-PROX temperature profiles of the Au/La2O3/Al2O3 catalysts reduced using different methods are shown in Figure 1. Interestingly, these profiles show considerable variation with the reduction method. The variation of the CO conversion with the reaction temperature reveals that the temperature of maximum CO conversion (Tmax) is also considerably affected by the reduction method. The Au/La2O3/Al2O3 (H) catalyst, reduced by the conventional thermal method under flowing hydrogen, exhibits the lowest Tmax and achieves 97.6% CO conversion at 61 °C [22]. The Tmax value shifts to 95 °C (98.1% CO conversion) in the case of the Au/La2O3/Al2O3 (S35) catalyst. Remarkably, the temperature window where high CO conversion is achieved is wider in the case of Au/La2O3/Al2O3 (S35) as compared to Au/La2O3/Al2O3 (H) (Table 1). These results highlight the favorable effects of chemical reduction with NaBH4. The maximum value of CO conversion and the drop in the CO conversion in CO-PROX at high temperatures are dependent on competition between H2 and CO oxidation, which can be controlled by the catalyst design.

Motivated by the positive influence of NaBH4 illustrated above, another aliquot of the as-prepared Au/La2O3/Al2O3 sample was treated with a higher NaBH4 concentration. This sample is denoted as Au/La2O3/Al2O3 (S115). However, in this case the maximum CO conversion dropped dramatically, accompanied by a shift of Tmax towards high temperatures. The Au/La2O3/Al2O3 (S5) catalyst, reduced with a very low concentration of NaBH4, exhibited similar catalytic performance to Au/La2O3/Al2O3 (H) [22]. These results suggest that low and high concentrations of NaBH4 are both ineffective for the chemical reduction of the catalyst.

A previous study revealed that an Au/CeO2 catalyst reduced by glycerol showed higher activity for the selective oxidation of glycerol to lactic acid, as compared to the catalyst thermally reduced under flowing hydrogen [24]. This prompted us to apply the glycerol reduction method to the Au/La2O3/Al2O3 catalyst. Figure 1 highlights the poor CO-PROX performance of the Au/La2O3/Al2O3 (G) catalyst, as indicated by the high Tmax value. The O2 conversion follows the same trend observed for the CO conversion (Figure 1). The chemically reduced samples exhibit slightly higher CO2 selectivity compared with Au/La2O3/Al2O3 (H) at low temperatures (Supplementary Information, Figure S1). The measured catalytic activities show that the CO-PROX temperature profile is sensitive to the catalyst reduction method. This could be attributed to the different characteristics of the gold nanoparticles formed in the different reduction processes.
Figure 1. CO-PROX performance of Au/La$_2$O$_3$/Al$_2$O$_3$ (□), Au/La$_2$O$_3$/Al$_2$O$_3$ (S35) (○), and Au/La$_2$O$_3$/Al$_2$O$_3$ (G) (⊗). Reaction conditions: 1 mol % CO, 1 mol % O$_2$, 50 mol % H$_2$, and 48 mol % He, F/W = 60,000 mL g$_{\text{cat}}^{-1}$ h$^{-1}$. CO-PROX: preferential oxidation of CO in H$_2$.

$^a$ The molar ratio of NaBH$_4$ to Au is included in parentheses; $^b$ The average particle size of gold was determined based on the TEM images; $^c$ The reaction conditions are same as those in Figure 1.
The NaBH₄-reduced sample (without further reduction under flowing hydrogen) exhibited a maximum of 92% CO conversion at 91 °C (95.7% O₂ conversion and 48.2% selectivity to CO₂) (Supplementary Information, Figure S2). The glycerol-reduced counterpart (without further reduction under flowing hydrogen) showed a maximum of 71% CO conversion at 155 °C. Without thermal treatment under H₂, the catalytic results are inferior. The inferior performance compared to subsequent H₂-reduced samples could be related mainly with incomplete reduction of gold. The effect of co-presence of H₂O and CO₂ in the feed was tested with the Au/La₂O₃/Al₂O₃ (S35) sample. A maximum of 93% CO conversion was observed at 97 °C (94.7% O₂ conversion and 49% selectivity to CO₂) (Supplementary Information, Figure S3).

2.2. Characterization of the Catalysts

2.2.1. TEM Analysis

The TEM measurements show that the gold particle size distribution varies significantly with the reduction method (Figure 2). Only small gold particles (2.9 ± 0.7 nm) were observed for the Au/La₂O₃/Al₂O₃ (H) catalyst [22]. On the other hand, comparatively larger gold particles (4.2 ± 4.9 nm) were found for the Au/La₂O₃/Al₂O₃ (S35) sample (Figure 2a). The effect of the gold particle size is reflected in the CO-PROX temperature profiles. The higher T_{max} measured for Au/La₂O₃/Al₂O₃ (S35) compared to Au/La₂O₃/Al₂O₃ (H) is consistent with the relatively larger Au particles in the S35 sample. The use of a higher concentration of NaBH₄ in the chemical reduction process resulted in large aggregates of gold particles in the Au/La₂O₃/Al₂O₃ (S115) sample (Figure S4b). As a result, the maximum CO conversion showed a marked decrease. Chemical reduction with glycerol resulted in an average Au particle size of 3.0 ± 0.6 nm for the Au/La₂O₃/Al₂O₃ (G) catalyst (Figure 2b), which, however, exhibited the lowest catalytic performance. The TEM measurements thus reveal that the average Au particle size, and hence the catalytic performance, can be altered by using different methods to reduce the catalyst. The X-ray diffraction (XRD) patterns of the Al₂O₃ and La₂O₃/Al₂O₃ supports (Figure S5) reveal a substantial decrease in the intensity of the alumina peaks, owing to the presence of lanthanum oxide on the alumina surface. The characteristic XRD peaks of La₂O₃ were not observed for La₂O₃/Al₂O₃, indicating that lanthanum oxide is present in an amorphous form on the alumina surface.

2.2.2. XPS Analysis

XPS measurements were performed in order to probe the effect of the catalyst reduction method on the characteristics of the resulting gold particles. The XPS spectra of Au/La₂O₃/Al₂O₃ (H) exhibits Au 4f⁷/₂ and Au 4f₅/₂ peaks at 83.8 and 87.4 eV, respectively (plot (a) in Figure 3), which are consistent with the binding energies of Au⁶⁺ [25–27]. All other samples exhibit binding energies shifted towards lower values compared to Au/La₂O₃/Al₂O₃ (H). The Au 4f⁷/₂ binding energy in the Au/La₂O₃/Al₂O₃ (S35) sample is shifted from 83.8 to 83.4 eV (plot (b) in Figure 3). The red shift in the binding energies of the chemically reduced samples indicates that the electronic properties of the gold nanoparticles in these samples differ significantly from those of the Au/La₂O₃/Al₂O₃ (H) catalyst. The significant variation in the CO-PROX temperature profiles corresponding to different catalyst reduction methods can thus be attributed to the variation of characteristics of gold nanoparticles and variation of adsorption/reactivity of different gases in the reaction mixture.

2.2.3. CO-DRIFTS Measurements

In order to understand the effect of the catalyst reduction method, CO adsorption experiments at 80 °C were analyzed by in situ DRIFTS measurements. The evolution of the bands corresponding to CO adsorbed on Au particles was studied by recording the spectra at different time points during He purging. Figure 4a shows the evolution of the DRIFT spectra corresponding to Au/La₂O₃/Al₂O₃ (H). We focus the analysis on the spectra measured after 3 min, which show the highest intensity in
The band with the highest intensity, located at 2107 cm\(^{-1}\), is attributed to CO linearly adsorbed on low-coordinated Au sites [28–31], and is accompanied by a low-intensity shoulder centered at 2025 cm\(^{-1}\). The intensity of these bands decreases after 5 min and a new very weak band appears at 1980 cm\(^{-1}\). Thereafter, the intensity of all bands decreases with time. Boccuzzi et al. [32] reported bands corresponding to CO adsorbed on small Au clusters in the 1950–2055 cm\(^{-1}\) range and attributed the band at 1990 cm\(^{-1}\) to the stronger adsorption of CO on small Au clusters than on larger Au particles. Therefore, the bands observed at 1980 and 2025 cm\(^{-1}\) can be attributed to CO strongly bonded to small gold clusters [26].

**Figure 2.** TEM images and gold size distributions of various Au/La\(_2\)O\(_3\)/Al\(_2\)O\(_3\) catalysts: (a) Au/La\(_2\)O\(_3\)/Al\(_2\)O\(_3\) (S35); (b) Au/La\(_2\)O\(_3\)/Al\(_2\)O\(_3\) (G).

**Figure 3.** Au(4f) XP spectra of various Au/La\(_2\)O\(_3\)/Al\(_2\)O\(_3\) catalysts: (a) Au/La\(_2\)O\(_3\)/Al\(_2\)O\(_3\) (H); (b) Au/La\(_2\)O\(_3\)/Al\(_2\)O\(_3\) (S35); (c) Au/La\(_2\)O\(_3\)/Al\(_2\)O\(_3\) (S115); (d) Au/La\(_2\)O\(_3\)/Al\(_2\)O\(_3\) (G).
The evolution of the spectra of the Au/La$_2$O$_3$/Al$_2$O$_3$ (S35) sample, obtained under identical conditions, is shown in Figure 4b. The band corresponding to CO linearly adsorbed on low-coordinated Au sites appears at 2112 cm$^{-1}$ after 3 min. The comparison of this spectrum with that measured at 3 min in Figure 4a reveals a clear blue shift of this band from 2107 to 2112 cm$^{-1}$, due to the treatment with NaBH$_4$. This blue shift indicates a stronger CO–Au$^0$ interaction [22], which is consistent with the highest CO conversion achieved by Au/La$_2$O$_3$/Al$_2$O$_3$ (S35). The weak bands observed at 1980 and 2025 cm$^{-1}$ for Au/La$_2$O$_3$/Al$_2$O$_3$ (H) (Figure 4a) are even less significant in the case of Au/La$_2$O$_3$/Al$_2$O$_3$ (S35) (Figure 4b). This indicates that the contribution from CO species strongly bonded to small gold clusters is very small in this case. The TEM results (Table 1) further corroborate this conclusion: upon chemical reduction with NaBH$_4$, the average gold size increases from 2.9 ± 0.7 to 4.2 ± 4.9 nm.

![Figure 4](https://example.com/figure4.png)

**Figure 4.** CO-DRIFT spectra of Au/La$_2$O$_3$/Al$_2$O$_3$ catalysts: (a) Au/La$_2$O$_3$/Al$_2$O$_3$ (H); (b) Au/La$_2$O$_3$/Al$_2$O$_3$ (S35). Lines a to e correspond to spectra recorded after CO adsorption at 80 °C and subsequent He purge for 3, 5, 10, 20, and 30 min, respectively. CO-DRIFT: diffuse-reflectance infrared Fourier-transform spectroscopy after CO adsorption.

The time evolution of the spectra recorded during CO-DRIFTS measurements on Au/La$_2$O$_3$/Al$_2$O$_3$ (S115) is presented in Figure 5a. The band attributed to CO linearly adsorbed on low-coordinated Au sites appears at 2114 cm$^{-1}$ after 3 min. The stronger blue shift of this band in Au/La$_2$O$_3$/Al$_2$O$_3$ (S115) than in Au/La$_2$O$_3$/Al$_2$O$_3$ (S35) (Figure 4b) could be attributed to the higher concentration of sodium borohydride employed for the chemical reduction process.
The comparison of the spectra measured at 10, 20, and 30 min in Figures 4b and 5a highlights a sharp decrease in the intensities of these bands for Au/La$_2$O$_3$/Al$_2$O$_3$ (S115). These results suggest that the amount of chemisorbed CO decreases when higher concentrations of NaBH$_4$ are used for the catalyst reduction. This explains the low CO-PROX performance of Au/La$_2$O$_3$/Al$_2$O$_3$ (S115) (Figure 1) and is consistent with the presence of large aggregates of gold particles, as observed in the TEM images (Figure S4b). Figure 5b shows the time evolution of the spectra recorded during CO-DRIFTS measurements for Au/La$_2$O$_3$/Al$_2$O$_3$ (G). The band corresponding to CO linearly adsorbed on low-coordinated Au sites is observed at 2107 cm$^{-1}$ after 3 min. The comparison between Figures 4a and 5b reveals a large difference in the intensity of the shoulder peak centered at 2025 cm$^{-1}$. This band corresponds to CO strongly bonded to small gold clusters [26]. Such contribution is negligible in the case of Au/La$_2$O$_3$/Al$_2$O$_3$ (G), in agreement with its low CO conversion (Figure 1).

2.2.4. DRIFTS Analysis during Methanol Decomposition

To assess the effect of the reduction method on the catalytic activity of the gold particles, the reactivity of adsorbed methanol was investigated by in situ DRIFTS. Methanol adsorption experiments were performed at 160 °C and the spectra were collected after subsequent He purging for 5 min (Figures 6–8). Several bands located in the 1018–1100 cm$^{-1}$ range (Figure 6) can be attributed to different methoxy species [33–36]. The bands centered at 1033 and 1056 cm$^{-1}$ exhibit the highest intensity in the case of Au/La$_2$O$_3$/Al$_2$O$_3$ (S35) (plot (c) in Figure 6), indicative of enhanced methanol...
adsorption on this catalyst. The adsorbed methoxy species undergoes further transformation into formate species.

Figure 6. In situ DRIFT spectra of Au/La₂O₃/Al₂O₃ catalysts after methanol adsorption at 160 °C and subsequent He purge for 5 min: (a) La₂O₃/Al₂O₃; (b) Au/La₂O₃/Al₂O₃ (H); (c) Au/La₂O₃/Al₂O₃ (S35); (d) Au/La₂O₃/Al₂O₃ (S115); (e) Au/La₂O₃/Al₂O₃ (G).

Figure 7. In situ DRIFT spectra of Au/La₂O₃/Al₂O₃ catalysts after methanol adsorption at 160 °C and subsequent He purge for 5 min: (a) La₂O₃/Al₂O₃; (b) Au/La₂O₃/Al₂O₃ (H); (c) Au/La₂O₃/Al₂O₃ (S35); (d) Au/La₂O₃/Al₂O₃ (S115); (e) Au/La₂O₃/Al₂O₃ (G).

The bands observed around 1371 and 1635 cm⁻¹ can be attributed to the ν₄ (OCO) and ν₃ (OCO) stretching modes of formate species, respectively (Figure 6) [33,34]. Note that the intensity of the band at 1635 cm⁻¹ is relatively high for Au/La₂O₃/Al₂O₃ (S35). The transformation of methoxy to formate is slightly more effective over Au/La₂O₃/Al₂O₃ (S35) than Au/La₂O₃/Al₂O₃ (H). The symmetric stretching modes of the methoxy CH bond, νₓ (C–H) and ν₆(C–H), have been reported in the 2819–2859 cm⁻¹ and 2920–2960 cm⁻¹ ranges, respectively [33,34]. The bands observed at 2844, 2865, 2922, 2935, 2970, and 2981 cm⁻¹ in Figure 7 could be attributed to the CH bond of formate species [33,34]. In particular, compared with Au/La₂O₃/Al₂O₃ (H) (plot (b) in Figure 7), these bands show higher intensity for Au/La₂O₃/Al₂O₃ (S35) (plot (c) in Figure 7), whereas their intensity is weaker in the case of Au/La₂O₃/Al₂O₃ (S115) (plot (d) in Figure 7).
Figure 7. In situ DRIFT spectra of Au/La$_2$O$_3$/Al$_2$O$_3$ catalysts after methanol adsorption at 160 °C and subsequent He purge for 5 min: (a) La$_2$O$_3$/Al$_2$O$_3$; (b) Au/La$_2$O$_3$/Al$_2$O$_3$ (H); (c) Au/La$_2$O$_3$/Al$_2$O$_3$ (S35); (d) Au/La$_2$O$_3$/Al$_2$O$_3$ (S115); (e) Au/La$_2$O$_3$/Al$_2$O$_3$ (G).

CO is formed upon further transformation of formate species on the gold catalyst. Figure 8 shows the variation in the intensity of the peak corresponding to CO adsorbed on gold (formed via methanol decomposition) among the different catalysts. In general, four bands could be observed for all samples. The band around 2112 cm$^{-1}$ corresponds to linear CO adsorbed on Au$^0$ particles [28,32]. The bands centered at 2053 [29,37] and 2076 cm$^{-1}$ [38] have been attributed to CO adsorbed on negatively charged gold clusters (Au$^{\delta^-}$-CO species), formed upon electron transfer from the support to the gold clusters [29,32,37,38]. Finally, the band at 2033 cm$^{-1}$ corresponds to bridge-bonded CO species on small gold clusters [32]. As expected, these bands were not observed for La$_2$O$_3$/Al$_2$O$_3$ (plot (a) in Figure 8).

The higher intensity of the band corresponding to CO adsorbed on negatively charged Au$^{\delta^-}$ sites [32,37] in the case of Au/La$_2$O$_3$/Al$_2$O$_3$ (S35) could be attributed to the chemical reduction with NaBH$_4$. Note the Au 4f$^7/2$ binding energy shift from 83.8 to 83.4 eV in Au/La$_2$O$_3$/Al$_2$O$_3$ (S35), relative to that of Au/La$_2$O$_3$/Al$_2$O$_3$ (H). This supports the presence of negatively charged Au$^{\delta^-}$ sites in Au/La$_2$O$_3$/Al$_2$O$_3$ (S35). The high-intensity bands in the DRIFTS spectra of methanol-derived CO (Figure 8) measured for Au/La$_2$O$_3$/Al$_2$O$_3$ (S35) indicate a higher reactivity of adsorbed methanol on this catalyst with respect to the other samples. The highest CO conversion obtained with Au/La$_2$O$_3$/Al$_2$O$_3$ (S35) in the CO-PROX temperature profiles (Figure 1 and Table 1) is in line with the results of the DRIFTS measurements during methanol decomposition. As could be noted from the Figure 1, the selectivity to CO$_2$ varies with the catalyst reduction method. The interactions of oxygen and hydrogen with gold particles are also very important to explain the activity of gold catalysts towards the CO-PROX reaction. Due to increased competition between CO and H$_2$ oxidation, the selectivity of CO$_2$ decreases with temperature. Moreover, the very weak intensity of the band at 2112 cm$^{-1}$ for Au/La$_2$O$_3$/Al$_2$O$_3$ (S115) (plot (d) in Figure 8), as compared with the other samples, suggests a very low reactivity of methanol adsorbed on Au$^0$ particles for this catalyst. The band at 2033 cm$^{-1}$, corresponding to the bridge-bonded CO species on small gold clusters [32], is also absent for this catalyst (plot (d) in Figure 8). This is in line with the TEM results, which revealed the presence of large aggregates of gold particles in this sample. Finally, Au/La$_2$O$_3$/Al$_2$O$_3$ (G) exhibits weaker bands at 2033, 2053, and 2076 cm$^{-1}$, as compared with Au/La$_2$O$_3$/Al$_2$O$_3$ (S35).

To summarize the insight obtained from the DRIFTS analysis of methanol-derived CO, Au/La$_2$O$_3$/Al$_2$O$_3$ (S35) exhibits stronger bands corresponding to methoxy/formate species and
methanol-derived CO compared with Au/La₂O₃/Al₂O₃ (H). The band centered at 2076 cm⁻¹, assigned to CO adsorbed on negatively charged Au⁵⁻ sites, also exhibits the highest intensity in the case of Au/La₂O₃/Al₂O₃ (S35) (plot (c) in Figure 8). Trueba et al. [19] and Boronat et al. [20] showed that negatively charged gold sites can favor CO oxidation by suppressing hydrogen conversion. In the normal CO-DRIFTS experiments, the band corresponding to CO linearly adsorbed on low-coordinated Au sites exhibits a blue shift from 2107 cm⁻¹ (Figure 4a) to 2112 cm⁻¹ (Figure 4b), indicating stronger CO–Au⁴⁺ interactions in the case of Au/La₂O₃/Al₂O₃ (S35). These results are in agreement with the DRIFTS spectra of methanol-derived CO. The Au/La₂O₃/Al₂O₃ (S35) sample exhibits the highest CO conversion in the CO-PROX experiments, which further corroborates the conclusions of the DRIFTS analysis. In addition to small clusters, medium and relatively large gold particles co-exist, as revealed by methanol-derived CO-DRIFTS. Therefore, the distribution of such gold particles among different samples cannot be ignored in the comparison of catalytic results.

3. Discussion

Interestingly, while the band at 2076 cm⁻¹ is merged with the main band centered at 2107 cm⁻¹ in the CO-DRIFTS spectra (Figures 4 and 5), the two bands are clearly separated in the DRIFTS spectra of methanol-derived CO (Figure 8). It can thus be concluded that the DRIFTS analysis of methanol-derived CO can be more informative than that of normal CO.

The comparison of plots (c) and (d) in Figure 6 highlights a lower intensity of the bands corresponding to adsorbed methoxy species (1033 and 1056 cm⁻¹) in the latter case. A similar trend is observed for the bands corresponding to formate and methanol-derived CO (compare plots (c) and (d) in Figures 7 and 8). These results show that higher concentrations of NaBH₄ lead to a decrease in the reactivity of methanol over Au/La₂O₃/Al₂O₃ (S115). This is consistent with the inferior CO-PROX performance of Au/La₂O₃/Al₂O₃ (S115). Moreover, a low concentration of NaBH₄ is also ineffective in the case of Au/La₂O₃/Al₂O₃ (S5) (Table 1). Therefore, it can be concluded that the concentration of NaBH₄ used in the chemical reduction process must be optimized. Chemical reduction with glycerol does not appear to have a positive influence on the reactivity of adsorbed methanol (plot (e) in Figure 6).

A similar conclusion can be drawn for the CO-PROX experiments. The FTIR analysis (Figure S6) shows the presence of bands related to glycerol and glycerol-derived intermediates [39–43], due to incomplete removal of glycerol from the catalyst surface, which resulted in the poor CO-PROX performance.

4. Materials and Methods

4.1. Preparation of Catalysts

The La₂O₃/Al₂O₃ support was prepared using the wet impregnation method [22]. An appropriate amount of La(NO₃)₃·6H₂O (≥99.9%, Sigma-Aldrich, St. Louis, MO, USA) was dissolved in ethanol (99.5%, Sigma-Aldrich, St. Louis, MO, USA) at room temperature, followed by addition of Al₂O₃ (Alfa Aesar, Brunauer-Emmett-Teller surface area, S_BET = 150 m² g⁻¹) and vigorous stirring for 1 h at room temperature. Ethanol was gradually removed with a rotary evaporator at 60 °C. The obtained powder was subsequently dried in an oven at 100 °C for 12 h and finally calcined in air at 500 °C for 5 h. Gold was loaded on the calcined La₂O₃/Al₂O₃ support using the DPU method (Supplementary Information).

The as-prepared Au/La₂O₃/Al₂O₃ sample was reduced by conventional thermal methods under flowing hydrogen at 200 °C for 2 h, and the product was denoted Au/La₂O₃/Al₂O₃ (H). Aliquots of the as-prepared sample were chemically reduced by different methods prior to thermal reduction with H₂ at 200 °C. The as-prepared sample was reduced with aqueous NaBH₄ at 25 °C. In a typical chemical reduction process, 0.150 g of the finely powdered as-prepared sample was mixed with deionized water and stirred vigorously for 30 min. Subsequently, an aqueous solution of NaBH₄ (with variable concentrations) was slowly added dropwise, followed by vigorous stirring at ambient temperature for 30 min. The reduction of gold was followed by an immediate color change from yellow to brown.
Excess water was removed by centrifugation. The obtained sample was thoroughly washed with deionized water several times and subsequently dried under a vacuum.

Chemical reduction was performed with different NaBH$_4$/Au molar ratios (5, 35, and 115). All samples were further reduced under flowing H$_2$ at 200 °C for 2 h, prior to the CO-PROX reaction. The products corresponding to NaBH$_4$/Au molar ratios of 5, 35, and 115 are denoted Au/La$_2$O$_3$/Al$_2$O$_3$ (S5), Au/La$_2$O$_3$/Al$_2$O$_3$ (S35), and Au/La$_2$O$_3$/Al$_2$O$_3$ (S115). Another portion of the as-prepared Au/La$_2$O$_3$/Al$_2$O$_3$ sample was used for chemical reduction with glycerol (CRG) [24] (Supplementary Information).

4.2. Characterization of Catalysts

The physicochemical properties of the prepared catalysts were probed with a variety of characterization techniques such as N$_2$ physisorption, powder X-ray diffraction (XRD), inductively coupled plasma atomic emission spectroscopy ICP-AES, TEM, DRIFTS, and XPS. The detailed procedure for each experiment is described in the Supplementary Information.

4.3. Catalytic Activity Tests

The CO-PROX performance of the catalysts was evaluated at atmospheric pressure employing a continuous fixed-bed reactor. In all cases, 0.10 g of the catalyst was loaded in the quartz reactor. It was brought into contact with a feed at a flow rate of 100 mL/min. The detailed procedures for the catalytic activity tests are described in the Supplementary Information.

5. Conclusions

We investigated the influence of the catalyst reduction method on the CO-PROX performance of Au/La$_2$O$_3$/Al$_2$O$_3$ catalysts. Aliquots of the same batch catalyst were reduced either with hydrogen by a conventional thermal method, or with NaBH$_4$ or glycerol by a chemical method. All chemically-reduced catalysts exhibited XPS peaks shifted towards lower binding energies. A blue shift of the IR band corresponding to CO linearly adsorbed on low-coordinated Au sites was observed in the case of Au/La$_2$O$_3$/Al$_2$O$_3$ catalysts reduced with NaBH$_4$. The size of the gold particles increased with the increasing amounts of NaBH$_4$ used for the chemical reduction. Glycerol and glycerol-derived intermediates were detected in the catalyst reduced with glycerol and were considered responsible for the poor CO-PROX performance of this system. At low temperatures, lower CO conversions were obtained over NaBH$_4$- or glycerol-reduced Au/La$_2$O$_3$/Al$_2$O$_3$ than hydrogen-reduced Au/La$_2$O$_3$/Al$_2$O$_3$ catalysts; however, high CO conversions were observed over a wider temperature range in the case of the Au/La$_2$O$_3$/Al$_2$O$_3$ catalyst reduced with an appropriate amount of NaBH$_4$. This catalyst showed the highest intensity of the IR band corresponding to CO adsorbed on negatively charged Au$^{5-}$ sites in the DRIFT analysis of methanol decomposition. Therefore, it can be concluded that chemical reduction with an appropriate amount of NaBH$_4$ enhances CO-PROX performance by improving the CO–Au interactions. However, an excessive amount of NaBH$_4$ has an adverse effect on the catalytic activity because of the formation of large aggregates of gold particles.
