Abstract: The opposing effects of high pressure (in the GPa range) and the Jahn-Teller distortion led to many intriguing phenomena which are still not well understood. Here we report a combined experimental-theoretical study on the high-pressure behavior of an archetypical Jahn-Teller system, copper difluoride (CuF2). At ambient conditions this compound adopts a distorted rutile structure of P21/c symmetry. Raman scattering measurements performed up to 29 GPa indicate that CuF2 undergoes a phase transition at 9 GPa. We assign the novel high-pressure phase to a distorted fluorite structure of Pbca symmetry, iso-structural with the ambient-pressure structure of AgF2. Density functional theory calculations indicate that the Pbca structure should transform to a non-centrosymmetric Pca21 polymorph above 30 GPa, which, in turn, should be replaced by a cotunnite phase (Pnma symmetry) at 72 GPa. The elongated octahedral coordination of the Cu2+ cation persists up to the Pca21→Pnma transition upon which it is replaced by a capped trigonal prism geometry, still bearing signs of a Jahn-Teller distortion. The high-pressure phase transitions of CuF2 resemble those found for difluorides of transition metals of similar radius (MgF2, ZnF2, CoF2), although with a much wider stability range of the fluorite-type structures, and lower dimensionality of the high-pressure polymorphs. Our calculations indicate no region of stability of a nanotubular polymorph observed for the related AgF2 system.

Keywords: copper; fluorides; Jahn-Teller effect; high pressure; polymorphism

1. Introduction

In 1937, Jahn and Teller showed that non-linear molecules exhibiting orbital degeneracy will undergo a distortion leading to a lower-energy, and orbitally non-degenerate, structure [1]. The so-called Jahn-Teller (JT) effect is particularly strong in systems containing divalent copper (3d9 electron count). Due to operation of the JT effect the first coordination sphere of the Cu2+ cation is distorted and most often forms an elongated instead of a regular octahedron with four shorter equatorial bonds and two longer axial ones [2–4].

The Jahn-Teller effect, also present in compounds containing the iso-electronic Ag2+ cation (4d9) [5], has a large impact on material properties such as magnetism [6], and electronic structure [7–9]. Even subtle distortions in the first coordination sphere of the JT-active cation can lead to large changes in material properties, as exemplified by the case of Ag2+-bearing fluorides [10,11]. Due to the fluxional nature of the Jahn-Teller effect many studies have been devoted to tuning this distortion either by chemical substitution [12–16], or by high external pressure [17–22].

In the latter case pressures above 1 GPa (=10 kbar) are used to induce substantial volume reduction which in turn leads to changes in the electronic and structural properties of the studied system. Large compression generally leads to the reduction of the JT distortion; it was found, however, that in compounds containing both Cu2+ and Mn3+ cations (the latter has a 3d4 configuration and is JT-active in the high-spin state) this distortion is surprisingly robust. In LaMnO3 JT-distorted domains persist...
up to the insulator-to-metal transition at 34 GPa [18], while for CsMnF$_4$ it was found that the effect is quenched only above 37 GPa when Mn$^{3+}$ cations enter the low-spin state [17]. The JT distortion seems to be even more stable in the case of divalent copper [19,20]. For CuWO$_4$ it initially decreases upon compression, but then increases abruptly during a phase transition at 9.9 GPa, and remains in place up to at least 20 GPa [19]. For Rb$_2$CuCl$_4$ it was found that the JT-distorted first coordination sphere of Cu$^{2+}$ is stiffer than the rest of the crystal structure, which leads to tilting distortions at high pressure [20].

In order to elucidate the complex interplay between the effect of large compression and the Jahn-Teller distortions we studied the high pressure phase transitions of copper difluoride (CuF$_2$). This compound is one of the simplest binary connections containing the Cu$^{2+}$ cation. It belongs to the family of metal difluorides, which have been extensively studied at high pressure [23–37]. Due to the operation of the JT effect CuF$_2$ adopts at ambient conditions a rarely-encountered crystal structure found only in one other compound (CrF$_2$) [38].

Here we present experimental and computational evidence that up to 100 GPa CuF$_2$ undergoes three phase transitions. The four lowest-enthalpy structures can be assigned to the rutile, fluorite, and cotunnite structure families, and the general phase transition sequence found for CuF$_2$ (rutile $\rightarrow$ fluorite $\rightarrow$ cotunnite) resembles that observed in other difluorides. However due to the operation of the Jahn-Teller effect the coordination of Cu$^{2+}$, as well as the dimensionality of the structures, differs from that found for other MF$_2$ systems. The high-pressure phase transitions of CuF$_2$ are reminiscent of those recently reported for its heavier analogue, AgF$_2$ [37], with the exception that a nanotubular phase found for AgF$_2$ is not observed [36].

2. Materials and Methods

Copper difluoride supplied by Sigma-Aldrich (Saint Louis, Missouri, United States) in a form of a powder (98% purity) was used in the study. Due to its hygroscopic nature all loadings were performed in an argon-filled glovebox with both water and oxygen content below 0.5 ppm. Measurements at ambient condition were performed on samples flame-sealed in quartz capillaries (OD 0.3 mm). The purity of the sample was confirmed by powder X-ray diffraction measurements (see Figure S1 in Supplementary Materials).

Raman spectra were acquired with the use of the Alpha300M+ system (Witec GmbH, Ulm, Germany). We used a 532 nm laser line (35 mW power at sample) delivered to a confocal microscope by a single-mode optical fiber. The signal was collected through a 20× long working distance objective, and passed through a multi-mode optical fiber to a lens-based spectrometer (Witec UHTS 300, f/4 aperture and a focal length of 300 mm) coupled with an Andor iDUS 401 detector (Oxford Instruments, Abingdon-on-Thames, UK). The spectra were collected with the use of a 1800 mm grating resulting in a 1.5 cm$^{-1}$ spectral resolution.

A total of three high-pressure runs were conducted with the use of a diamond anvil cell (DAC) supplied by D’Anvils (Hod-Hasharon, Israel). The DAC was equipped with low-fluorescence 1a diamonds (single-beveled with culet sizes of 400 µm and 500 µm) and a pre-indentated stainless-steel gasket (35 µm thick). The gasket hole of 250 µm was drilled by spark-erosion. The pressure was determined from the shift of the R1 ruby fluorescence line [39]. The position of Raman bands was established with Fityk 0.9.8 software (Marcin Wojdyr, Poland) by background subtraction and fitting of the observed spectra with Lorentzian profiles [40].

Periodic DFT calculations utilized the rotationally-invariant DFT+U method [41], with the PBE exchange-correlation functional [42]. We set the $U$ and $J$ values of the DFT+U method to 7 eV and 0.9 eV, respectively, as suggested in a recent study on KCuF$_3$ [43]. These value are similar to those used in other studies [44,45]. The employed method yielded lattice constants and Cu-F bond lengths overestimated by less than 2% compared to the experimental structure of CuF$_2$ determined at low temperature [46].
The projector–augmented-wave (PAW) method was used [47], as implemented in the VASP 5.4 code. The cutoff energy of the plane waves was set to 920 eV with a self-consistent-field convergence criterion of $10^{-6}$ eV. Valence electrons (Zn, Cu: 3d, 4s; F: 2s, 2p) were treated explicitly, while standard VASP pseudopotentials (accounting for scalar relativistic effects) were used for the description of core electrons. The k-point mesh was set at $2\pi \times 0.03$ Å$^{-1}$. All structures were optimized using a conjugate-gradient algorithm until the forces acting on the atoms were smaller than 5 meV/Å. For each structure the optimization was performed for the lowest-energy spin state, that is: (i) AFM ordering within [CuF$_{4/2}$] sheets for P$_2_1$/$c$, P$bca$, and Pca$2_1$; (ii) FM ordering within chains of the cotunnite $Pnma$ structure; and (iii) AFM ordering within nanotubes present in the $Pbcn$ polymorph.

Evolutionary algorithm searches were performed at 20, 60, and 100 GPa for $Z = 8$ with XtalOpt software (version r9 [48]) which was coupled with the DFT+U method described above. The searches yielded the P$\bar{b}ca$/Pca$2_1$/Pnma structures as the lowest-enthalpy polymorphs of CuF$_2$ at 20/60/100 GPa, in accordance with results presented in this work.

Calculations of Γ-point vibration frequencies were conducted in VASP within the DFT finite-displacement method (0.007 Å displacement was used) and a tighter SCF convergence ($10^{-8}$ eV). Visualization of all structures was performed with the VESTA software package [49]. For symmetry recognition we used the FINDSYM program [50]. Group theory analysis of the vibrational modes was performed with the use of the Bilbao Crystallographic Server [51].

3. Results

3.1. Ambient Pressure

At ambient conditions CuF$_2$ crystallizes in a structure belonging to the rutile-type family. The rutile (TiO$_2$) aristotype, adopted by most of the first row transition metal difluorides, has tetragonal (P$4_2$/mnm) symmetry, and features a six-fold coordination of the metal center (Figure 1a). Due to operation of a collective JT distortion copper difluoride adopts a structure with lower symmetry (monoclinic, P$2_1$/n), exhibiting a $4 + 2$ coordination of Cu$^{2+}$ [46,52–55]. This structure, shown in Figure 1b, can be also transformed to a P$2_1$/c setting (Figure 1c) which more clearly illustrates the presence of puckered sheets of [CuF$_{4/2}$] stoichiometry. These sheets host a relatively strong antiferromagnetic (AFM) interaction between the neighboring Cu$^{2+}$ sites [56], which together with a weak ferromagnetic (FM) inter-layer coupling leads to a spin-canted 2D AFM state below 70 K [46,57,58]. Hereinafter when referring to the ambient pressure rutile-type structure of CuF$_2$ we will use the P$2_1$/c setting.

![Figure 1](image_url)

*Figure 1.* (a) The rutile aristotype (P$4_2$/mnm); (b) The CuF$_2$ structure in the P$2_1$/n setting; and (c) the same structure in the P$2_1$/c setting. Blue/red balls mark metal/ligand atoms (Cu/F in case of CuF$_2$); for CuF$_2$ dark blue cylinders depict short Cu-F bonds (1.9 Å); light blue cylinders depict long bonds (2.3 Å).

Up to date various techniques have been employed in the characterization of CuF$_2$, but to our knowledge there are no reports concerning the Raman spectrum of this material. Group theory analysis of the P$2_1$/c structure of copper difluoride ($Z = 2$), performed with the use of the Bilbao...
Crystallographic Server [51], indicates that among the 18 \( \Gamma \)-point vibrational modes \((3A_g + 6A_u + 3B_g + 6B_u)\) six are Raman-active \((3A_g + 3B_g)\).

We performed calculations of the \( \Gamma \)-point frequencies for the \(P2_1/c\) structure of \(\text{CuF}_2\) with the use of the density functional theory with the inclusion of the on-site Coulomb repulsion (DFT+U method, for calculation details see Materials and Methods). The resulting values are compared in Table 1 with those obtained from ambient-pressure Raman measurements (Figure 2). The lowest-energy \(A_g\) mode is not observed experimentally as its predicted frequency of 70 cm\(^{-1}\) lies below the detection limit of our Raman setup. Two \(B_g\) and two \(A_g\) modes with calculated frequencies in the 200–350 cm\(^{-1}\) range can be assigned to the four strongest Raman bands found in experiment (Figure 2). The frequency of these four bands is on average only 4.7% higher than those predicted theoretically. Finally, the highest-frequency \(B_g\) mode is found experimentally at a Raman shift 8.0% higher than predicted from DFT+U. One additional band at 496 cm\(^{-1}\) is observed in the Raman spectrum of powder \(\text{CuF}_2\). This transition, marked by a star in Figure 2, can be tentatively assigned as an overtone of the strongest \(A_g\) mode at 254 cm\(^{-1}\), or as a combination mode of two \(B_g\) vibrations at 221 and 293 cm\(^{-1}\).

Table 1. Comparison of calculated \((\omega_{\text{th}})\) and experimental \((\omega_{\text{exp}})\) \( \Gamma \)-point Raman frequencies (in cm\(^{-1}\)) of the rutile-type \(P2_1/c\) structure of \(\text{CuF}_2\) at ambient pressure. No scaling was applied to the calculated frequencies.

Figure 2. Raman spectrum of powder \(\text{CuF}_2\) at ambient condition.

The good accordance between the experimental and theoretical Raman frequencies gives confidence that DFT+U method employed here can accurately simulate the pressure dependence of the frequencies of Raman active modes of \(\text{CuF}_2\). In particular the theoretical values should fall close to the experimental ones after scaling by 1.047. This is indeed the case, as will be shown in the subsequent section

3.2. Raman Scattering up to 29 GPa

Powder samples of \(\text{CuF}_2\) were loaded into the DAC and compressed to 29.4 GPa with Raman spectra taken upon compression in ca. 2 GPa intervals (for more details see Materials and Methods section). At high pressure all of the observed Raman modes shift to higher frequencies and broaden
Around 9 GPa a splitting of the highest-frequency $A_g$ band is observed, as well as a new band appears at 185 cm$^{-1}$ signaling changes in the structure of CuF$_2$ (Figure 3b, see also Figure S2 in Supplementary Materials, for a deconvolution of the Raman spectra at 19.6 GPa). As we will argue below the changes in the Raman pattern at 9 GPa are a result of a phase transition from the ambient pressure rutile-type $P2_1/c$ structure to a fluorite-like polymorph of $Pbca$ symmetry.

Before we discuss this transition we note that the pressure dependence of the Raman frequencies below 9 GPa is in very good agreement with that predicted theoretically for the $P2_1/c$ structure. Interestingly, the lowest-frequency $A_g$ mode (not observed experimentally) is predicted to soften upon compression. This behavior resembles the one found in compounds adopting at ambient conditions the rutile aristotype, for example ZnF$_2$ [24], CoF$_2$ [28,31], FeF$_2$ [30], and MnF$_2$ [33]. In these systems the pressure-induced softening of a low-frequency $B_{1g}$ mode leads to a second order phase transition from the $P4_2/mnm$ structure to a CaCl$_2$-type polymorph ($Pnnm$ symmetry, $Z = 2$). The latter structure can be obtained from the rutile aristotype by introducing tilts of the MF$_6$ octahedra about the $c$ axis (compare Figure 1a).

Figure 3. (a) Raman spectrum of powder CuF$_2$ at selected pressures (their values are given in GPa), the spectra corresponding to the rutile $P2_1/c$ phase are shown in black while those assigned to the fluorite-type $Pbca$ phase are shown in blue; and (b) pressure dependence of the frequency of the Raman bands (circles for experiment: black—$P2_1/c$; blue—$Pbca$; lines for DFT+U calculations: red—$P2_1/c$; green—$Pbca$). Arrows mark the appearance of a new low-frequency band and splitting of the $A_g$ band. Asterisks in (a) mark the $B_g$ band originating from traces of the $P2_1/c$ structure still present above the phase transition, while stars in (b) indicate the pressure dependence of the $A_g$ overtone or $B_g$ combination mode of rutile CuF$_2$ (see text). The calculated frequencies were scaled by 1.047.

One might, therefore, expect that the ambient-pressure $P2_1/c$ structure of CuF$_2$ will undergo a similar transition. Indeed in our calculations we find another structure of $P2_1/c$ symmetry and $Z = 2$ which is related to the ambient-pressure structure by rotation of the CuF$_6$ units about the $a$ axis (compare Figure 1c). At 9 GPa this polymorph, which we will refer to as $P2_1/c$ (I), has a marginally lower enthalpy than $P2_1/c$ ($\Delta H = -1.4$ meV per f.u.). We note, however, that the frequency of its Raman modes is very similar to that of the original $P2_1/c$ structure (differences not exceeding 3%), with the exception of the lowest-frequency $A_g$ mode which is shifted from 11 cm$^{-1}$ for $P2_1/c$ to 74 cm$^{-1}$ for $P2_1/c$ (I). Hence the Raman bands predicted for $P2_1/c$ (I) cannot account for the changes observed in the spectral region above 100 cm$^{-1}$.
A possible candidate for the high-pressure polymorph of CuF$_2$ is a fluorite type structure of Pbca symmetry ($Z = 4$, Figure 4a), which is adopted at ambient conditions by AgF$_2$ [59,60]. Indeed, as can be seen in Figure 3b, in the whole pressure range studied there is a good match between the frequencies of the Raman-active modes predicted for this structure and those observed in experiment. Therefore the phase transition at 9 GPa can be assigned to the transformation from $P2_1/c$ to Pbca. This notion is further corroborated by DFT+U calculation which predict a phase transition between these two CuF$_2$ polymorphs at the same pressure (vide infra). Interestingly the 2D puckered sheets present in $P2_1/c$ are retained in the Pbca polymorph (Figure 4a).

Figure 4. (a) The fluorite-type Pbca structure CuF$_2$ (for clarity only the four shortest Cu-F bonds are shown); (b) the coordination of Cu$^{2+}$ in Pbca calculated at 9 GPa; and (c) the coordination of Cu$^{2+}$ in $P2_1/c$ calculated at 9 GPa; Cu-F distances are given in Å.

The Pbca structure can be related to the fluorite aristoype (CaF$_2$, $Fm-3m$ symmetry, $Z = 4$) [37]. Therefore the high-pressure transition from rutile-type $P2_1/c$ to Pbca is analogous to the rutile-fluorite transition found in difluorides containing non-JT ions (e.g., MgF$_2$ [23], ZnF$_2$ [26], CoF$_2$ [31]). The Pbca structure exhibits a 4 + 2 + 2 coordination of Cu$^{2+}$ with two Cu-F contacts considerably longer (≈30%) than the remaining six. Therefore the number of neighbors in the first coordination sphere of Cu$^{2+}$ (6) remains unchanged upon transition from $P1/c$ to Pbca.

3.3. Calculations up to 100 GPa

In order to further validate the interpretation of experiment, and to extend our study to higher pressures we performed DFT+U calculations for various CuF$_2$ phases up to a pressure of 100 GPa. Apart from the $P2_1/c$ and Pbca polymorphs mentioned earlier we took into account three other possible structures: Pca2$_1$ ($Z = 4$, Figure 5a), Pbcn ($Z = 8$, Figure 5b), and Pnma ($Z = 4$, Figure 5c). These structure were proposed as high-pressure polymorphs of AgF$_2$ with Pca2$_1$ and Pbcn indeed observed experimentally [36,37]. We also searched for other candidate structures with the use of the XtalOpt evolutionary algorithm [48], but did not find any structure competitive in terms of enthalpy with the five mentioned above.

Figure 5. Possible high-pressure structures of CuF$_2$ (a) Pca2$_1$ ($Z = 4$); (b) Pbcn ($Z = 8$); and (c) Pnma ($Z = 4$). For clarity only the four shortest Cu-F bonds are shown.
For AgF$_2$, the Pca$_{21}$ polymorph (HP1-AgF$_2$) is stable between 9 and 14 GPa (Figure 5a). This structure arises from a phonon instability of the ambient-pressure Pbca polymorph stable up to 9 GPa [37]. These two fluoride-type structures are closely related and both feature 2D sheets. The main difference between Pca$_{21}$ and Pbca is that, in the former structure, the metal cations are displaced out of the plane formed by the four nearest F atoms which results in a non-centrosymmetric coordination of the metal cation.

The Pbcn polymorph (HP2-AgF$_2$), observed for AgF$_2$ from 15 GPa up to at least 36 GPa [36,37], features nanotubes built from AgF$_4$ plaquettes distorted in the same way as in Pca$_{21}$ (Figure 5b). Finally, the Pnma structure consists of chains built from analogous AgF$_4$ units (Figure 5c). The Pnma phase is isostructural with the cotunnite ($\alpha$-PbCl$_2$) arista type, a structure featuring nine-fold coordination of the metal center. The $\alpha$-PbCl$_2$ polytype is adopted by many metal difluorides at large compression [27]. The Pbcn phase also belongs to the cotunnite structure family [37].

Optimization of the Pca$_{21}$, Pbcn, and Pnma structures assuming a CuF$_2$ stoichiometry does not lead to changes in the bonding topology between fluorine atoms and metal centers with respect to that found in the respective AgF$_2$ polymorphs. By performing calculations at various pressures we were able to extract and compare the enthalpy of each of the five studied phases up to 100 GPa. This structure arises from a phonon instability of the ambient-pressure Pbca polymorph stable up to 9 GPa [37]. These two fluoride-type structures are closely related and both feature 2D sheets. The main difference between Pca$_{21}$ and Pbca is that, in the former structure, the metal cations are displaced out of the plane formed by the four nearest F atoms which results in a non-centrosymmetric coordination of the metal cation.

For CuF$_2$, the Pca$_{21}$ polymorph (HP1-CuF$_2$) is stable between 9 and 14 GPa (Figure 6a). Calculations indicate that at 9 GPa CuF$_2$ should undergo a phase transition from P2$_1$/c to Pbca, in accordance with the high-pressure experimental results presented in the previous section. We predict a substantial volume decrease (14%) at this transition (Figure 6b). Upon further compression Pbca is predicted to transform into the Pca$_{21}$ polymorph at 30 GPa. The smooth enthalpy change upon the transition, as well as the lack of a volume discontinuity suggests that this is a second order transition, in analogy with what was previously reported for an analogous transition in AgF$_2$ [37]. The last structural transition, between Pca$_{21}$ and Pnma is predicted to occur at 72 GPa with a 3.6% volume reduction. We note that in contrast to the P2$_1$/c, Pbca, and Pca$_{21}$ polymorphs Pnma features 1D chains. The calculations indicate no region of stability for the nanotubular Pbcn phase which is observed for AgF$_2$.

For the rutile (P2$_1$/c) and fluorite (Pfca) phases of CuF$_2$ we fitted the calculated volumes with the Birch-Murnaghan equation of state [61]. The obtained values of the bulk modulus (B$_0$), given in Table 2, indicate that, surprisingly, the low-pressure P2$_1$/c structure is less compressible than the rutile-like polymorph (at the same time P2$_1$/c has a larger volume than Pfca). The B$_0$ values calculated
for the CuF₂ phases are about 30% lower than those calculated for the rutile and fluorite phases of 
ZnF₂ (Table 2). Given the fact that Zn²⁺ has nearly identical radius to Cu²⁺ \( R_{\text{oct}}(\text{Zn}^{2+}) = 0.88 \ \text{Å}; \ \text{R}_{\text{oct}}(\text{Cu}^{2+}) = 0.87 \ \text{Å} \) [62], one would expect a similar value of \( B_0 \) for both CuF₂ and ZnF₂. The lower bulk moduli found for copper difluoride phases most likely stems from the 2D character of its structures which results in facile compression in the direction perpendicular to the sheets. This notion is corroborated by the fact that both \( P2_1/c \) and \( Pmca \) exhibit anisotropic compression with the inter-sheet distances more compressible than the intra-sheet ones (see Figure S3 in the Supplementary Materials).

Table 2. The bulk modulus in GPa (\( B_0 \)), and its derivative (\( B_0' \)) calculated for CuF₂ phases. Results obtained for the rutile (\( P4_2/\text{mmn} \)) and fluorite (\( Fm-3m \)) structures of ZnF₂ are shown for comparison.

1 DFT calculations with the PBE functional from ref. [32].

We now move to the analysis of the bonding pattern in the high-pressure polymorphs of CuF₂. As can be seen in Figure 7a the Jahn-Teller distortion in \( P2_1/c \) is reduced upon compression. This observation is further corroborated by comparing the compressibility of M-F distances in CuF₂ and ZnF₂ (see Figures S4 and S5 in Supplementary Materials). As mentioned earlier the number of neighbors in the first coordination sphere of Cu²⁺ remains at six upon the \( P2_1/c \) to \( Pmca \) transition. This can be well seen in the pressure dependence of Cu-F contacts shown in Figure 7a. It is noteworthy to point out that the distortion of the CuF₆ octahedron becomes larger at the transition. This signals an increase of the JT effect upon the \( P2_1/c \)–\( Pmca \) phase transition in analogy to what was found for CuWO₄ [19].

![Figure 7](image-url)

**Figure 7.** (a) Calculated pressure dependence of the Cu-F distances in the high-pressure polymorphs of CuF₂. The coordination of the Cu²⁺ cation in (b) \( Pmca \) at 30 GPa; (c) \( Pca2_1 \) at 50 GPa; and (d) \( Pnma \) at 72 GPa; together with (e) the Zn²⁺ coordination in the \( Pnma \) phase of ZnF₂ optimized at 72 GPa. Distances are given in Å; numbers in parentheses indicate the percentage difference between the Cu-F and Zn-F distances in the \( Pnma \) polymorphs.
The elongated octahedral coordination is also retained during the \textit{Pbca-Pca2}_1 transition, although due to additional secondary contacts the CuF\textsubscript{6} units become more distorted in \textit{Pca2}_1 (compare Figure 7b,c). Upon compression of \textit{Pca2}_1 one of the Cu-F contacts in the second coordination sphere of Cu\textsuperscript{2+} shortens considerably (by 22\% from 30 to 72 GPa), and at 72 GPa is only 6.7\% longer than the longer of the two Cu-F axial bonds.

The most dramatic changes in the coordination of Cu\textsuperscript{2+} are seen upon the \textit{Pca2}_1-\textit{Pnma} transition. The four short equatorial bonds, and the two axial ones elongate upon the transition. Additionally, the longer axial bond becomes nearly equal in length with one of the secondary Cu-F contacts (compare Figure 7c,d). As a result the first coordination sphere of Cu\textsuperscript{2+} can no longer be described as a distorted octahedron, but rather as a capped trigonal prism (coordination number equal to 7). In fact, it closely resembles that of the Zn\textsuperscript{2+} cation in the same \textit{Pnma} phase of ZnF\textsubscript{2} (Figure 7d,e). This might suggest that the Jahn-Teller effect, present in the \textit{P2}_1/c, \textit{Pbca}, and \textit{Pca2}_1 phases, is quenched in the \textit{Pnma} phase.

However, the four shortest Cu-F bonds in \textit{Pnma} (dark blue cylinders in Figure 7d) are 5\% to 8\% shorter than the corresponding distances in ZnF\textsubscript{2}, while the three longer bonds (light blue cylinders) are longer by approximately the same amount. Those differences in the coordination spheres of Cu\textsuperscript{2+} and Zn\textsuperscript{2+} resemble the Jahn-Teller effect found for the octahedral environment. Therefore, it is highly probable that the JT effect is still operational in the \textit{Pnma} phase of CuF\textsubscript{2}, although in a different coordination environment. We note that in our calculations that magnetic moments on Cu\textsuperscript{2+} atoms (m\textsubscript{Cu}) as well as a substantial the band gap (E\textsubscript{g}) are retained in the \textit{Pnma} polymorph even at 100 GPa (m\textsubscript{Cu} = 0.83 \muB, E\textsubscript{g} = 2.4 eV). Moreover the shape of the spin-density of \textit{Pnma} at this pressure (Figure S6 in Supplementary Materials) suggests occupation of a local \textit{d(x\textsuperscript{2} − y\textsuperscript{2})} orbital on each Cu\textsuperscript{2+} site, in analogy with the situation found for an elongated octahedral coordination of a \textit{d\textsuperscript{5}} cation.

4. Discussion

The high-pressure transformations of CuF\textsubscript{2} can be compared to that of other metal difluorides, in particular those containing cations of similar size \([62]\): Mg\textsuperscript{2+} (0.86 Å), Zn\textsuperscript{2+} (0.88 Å), and Co\textsuperscript{2+} (0.89 Å) in the high-spin state). The MF\textsubscript{2} systems (M = Mg, Zn, Co), all adopting the undistorted rutile structure at ambient conditions, exhibit a similar phase transition sequence upon compression \([23,26,31]\): rutile (\textit{P4\textsubscript{2}/mnn}) \rightarrow \textit{CaCl\textsubscript{2}}-type (distorted rutile, \textit{Pnma}) \rightarrow \textit{HP-PdF\textsubscript{2}} (distorted fluorite, \textit{Pa-3}) \rightarrow \alpha-PbCl\textsubscript{2} (cotunnite, \textit{Pnma}). Only in the case of CoF\textsubscript{2} an additional undistorted fluorite phase (\textit{Fm-3m}) exhibits a region of stability between the \textit{HP-PdF\textsubscript{2}} and \alpha-PbCl\textsubscript{2} phases \([31]\).

The corresponding transition pressures are summarized and compared with that of CuF\textsubscript{2} in Figure 8. The subsequent high-pressure transitions of CuF\textsubscript{2} from rutile \textit{P2}_1/c to fluorite \textit{Pbca} and \textit{Pca2}_1 up to cotunnite \textit{Pnma} matches that found for MF\textsubscript{2} (M = Mg, Zn, Co). The differences between copper difluoride and other systems lies in the lower symmetry of CuF\textsubscript{2} phases, which is a result of the JT effect. Moreover, for CuF\textsubscript{2}, the stabilization pressure of the cotunnite structure is shifted to much higher pressures compared to the MF\textsubscript{2} systems.

The \textit{Pbca} \rightarrow \textit{Pca2}_1 phase transition predicted to occur at 30 GPa for CuF\textsubscript{2} is analogous to that found at 9 GPa for its heavier analogue, AgF\textsubscript{2} \([37]\). The difference between the two compounds lies in the fact that for CuF\textsubscript{2} the \textit{Pca2}_1 polymorph is predicted to transform to the cotunnite \textit{Pnma} phase at 72 GPa, while for AgF\textsubscript{2} \textit{Pca2}_1 transforms to a nanotubular cotunnite-like \textit{Pbca} structure at 14 GPa. Calculations on the AgF\textsubscript{2} system indicate that \textit{Pnma} and \textit{Pbca} polymorphs become nearly degenerate in terms of enthalpy above 50 GPa \([37]\). We do find for CuF\textsubscript{2} that \textit{Pbca} is more stable than \textit{Pnma} below 64 GPa (see Figure 6a), but at this pressure both are less stable than the \textit{Pca2}_1 polymorph, and above this pressure \textit{Pnma} is more stable.

In conclusion, Raman measurements indicate that CuF\textsubscript{2} undergoes a phase transition at 9 GPa between the rutile-type \textit{P2}_1/c structure and the fluorite-type \textit{Pbca} structure. This result is corroborated by DFT+U calculations, which further indicate that, at 30 GPa, it should transform to a structurally-related \textit{Pca2}_1 polymorph. Upon further compression copper difluoride should adopt a cotunnite \textit{Pnma} structure at 72 GPa. Due to the low dimensionality of its high-pressure phases CuF\textsubscript{2}
should be more compressible than ZnF$_2$. Surprisingly for CuF$_2$ high pressure induces a transition from 2D structure (P$2_1/c$, Pca$_2$, Pca$_2$) to a 1D polymorph (Pnma).

The classical Jahn-Teller effect leading to an elongated octahedral coordination of Cu$^{2+}$ can be observed in the P$2_1/c$, Pca, and Pca$_2$ phases up to 72 GPa. Upon entering the Pnma phase at that pressure the first coordination sphere of Cu$^{2+}$ changes substantially, but the Jahn-Teller effect seems to be still operational. We hope that our results will motivate further studies into CuF$_2$ subject to high pressure, in particular measurements which will enable direct probing of the local electronic structure of the Cu$^{2+}$ cations.
