Abstract: This study proposes a parameter optimization method for identifying the optimal nonlinear parameters of a miniature transducer with a metal membrane. Specifically, a nonlinear lumped parameter model (LPM) of a miniature transducer that accounts for predicted displacement in a manner that is consistent with the displacement measured by a high-precision capacitance micro-displacement sensor is proposed. To avoid application of the proposed optimization method to an ill-posed problem, this paper proposes a constrained equation that is derived from the relationships of nonlinear parameters. The Broyden–Fletcher–Goldfarb–Shanno (BFGS) algorithm is used to minimize the objective function in order to obtain an appropriate solution from the proposed nonlinear LPM. The numerical simulation results and a discussion of the experiments are presented. The numerical simulation verification demonstrated that the presented method can estimate the suitable nonlinear parameters for the displacement with errors. With regard to empirical verification, the empirical investigations showed that the proposed method could accurately assess the nonlinear parameters of a miniature transducer with a metal membrane.

Keywords: miniature transducer; nonlinear parameter; optimization; capacitance micro-displacement sensor

1. Introduction

The nonlinear parameters of a miniature transducer play an important role in the sound quality of mobile devices. These parameters can be responsible for the output performance of a miniature transducer. Special techniques can be used to measure the harmonic and intermodulation distortion of signals excited by single-, dual-, and multi-tone sine waves/signals. In the last decade of research on transducers, multiple methods have been proposed to predict harmonic and intermodulation distortion, and these methods are useful in transducer design. The traditional method used to predict the sound pressure, diaphragm displacement, and electric current of a moving-coil transducer comprise the lumped parameter model (LPM) [1], which allows for the comprehensive analysis of a transducer’s model parameters. The traditional LPM contains an important set of six parameters, namely, voice-coil inductance $L_e$, electrical resistance $R_e$, mechanical mass $M_m$, mechanical resistance $R_m$, mechanical stiffness $K_m$, and force factor $B_l$, which are used to represent the electrical and mechanical domains of the moving-coil transducer. The LPM helps to design a transducer quickly and accurately to estimate its performance, and it is currently the most common method used to assess the transducer quality.
Electroacoustic measurement is characterized by multiple categories and methods [2]. Each measurement provider formulates different instruments and procedures for transducers with different dimensions. Different methods have been applied by scientists in the past, such as the added mass method [1,3] and the optimization method [4], for transducer’s linear parameters estimation. When the miniature transducer is driven in the large signal domain, abnormal vibrations have been observed due to large input signal and increased voltage imposed on voice coil for its displacement [5]. The moving diaphragm that was activated by pneumatic pressure [6] demonstrated that the transducer’s model parameters cannot remain linear, but the performance of the transducer can be evaluated by position-dependent parameters [7] as nonlinear parameters. In 1990, Klippel [8] proposed a dynamic measurement system and used a high-precision laser vibrometry and noise signal to measure the linear and nonlinear parameters of a transducer LPM. The nonlinear parameters generate nonlinear effects, such as harmonic and intermodulation distortion; thus, the system that was proposed by Klippel is often used for transducer development, production, quality control, and diagnostics [5,9]. Faifer et al. [10] proposed a nonlinear LPM to identify the coefficient of stiffness $K_m(x)$ and the force factor $(Bl)$ and investigated the reduction of 2nd–3rd harmonic distortions by transducer parameter linearization. A simulation method [11] uses finite element analysis for the identification of the nonlinear parameters early, which is the meaningful way of characterizing the transducer in the product development process. In 2001, Mihelich proposed [12] a parameter optimization method for minimizing the cost function between the predicted sinusoid type of displacements and the modeled response for obtaining nonlinear parameters. More proposed algorithms [13,14] based on the system identification method are used to minimize the errors between the output response and the system output for obtaining optimal nonlinear parameters. However, the relative clay mass or sealed box were selected based on the transducer dimensions, thus the above methods increased the mechanical mass or acoustical stiffness of the transducer, which are not applicable to miniature and small transducers.

Modern miniature transducers have been developed as part of the trend toward the miniaturization and they have been fabricated with metal membranes due to the low weights and dynamic responses. The displacement measurement errors caused by diaphragm vibration in a miniature transducer with a metal membrane may encounter errors due to optical refraction during laser measurements. Hence, there is the need to increase diaphragm reflection accuracy by making a mark on the diaphragm. The measurement of displacement is the basis of measuring position, velocity, acceleration, stress, force, pressure, proximity, thickness, etc. A displacement sensor measures the distance between the sensor and an object to be detected by identifying the displacement over a variety of elements and converting it into a distance. In 2012, Lei et al. [15] proposed a quartz crystal capacitive sensor that consists of a uniplanar scattering-field capacitance and a piezoelectric resonator for high sensitivity response (3.05 Hz/μm in the range of 20–200 μm). In the same year, Kang et al. [16] proposed a low-power high-resolution capacitive sensor for fast vibration measurements. As shown in the studies that were reviewed above, the high precision and better resolution of capacitive sensor testing were the main reasons for measuring the diaphragm displacement of a miniature transducer with a composite metal membrane in this study.

To identify the nonlinear parameters, among the conventional optimization methods for parameter estimation, such as the Stochastic Gradient Descent (SGD) [17], RMSProp and ADAM [18], Conjugate Gradient method (CGM) [19], and Broyden Fletcher Goldfarb Shanno Method (BFGS) [20], are the incremental gradient descent based iterative method for optimizing a differentiable objective function. The gradient descent algorithm updates the optimized parameters to minimize the objective function by taking small learning steps in the direction of the negative gradient of the loss of the objective function. The CGM searches from the conjugate direction along the negative gradient with the characteristics of double convergence from SGD; moreover, SGD and CGM use a single learning rate for all of the parameters. The RMSProp can improve by using learning steps that are different for different parameters and that can automatically adapt to the objective function being optimized.
was also utilized to improve the step size for accelerating iteration times. The transducer’s equation of
The behaviors of these two parts are described by the mechanical mass, stiffness, and damping.

The BFGS method is one of the famous methods that belongs to quasi-Newton methods [20], which
generally requires much fewer iterations to reach the local minimum as compared to CGM and
SGM. In this paper, the miniature transducer’s differential equation was established and the use of
the Broyden–Fletcher–Goldfarb–Shanno (BFGS) algorithm [20] to identify the nonlinear parameters
simultaneously during the optimization process was proposed in this study. The Brent method [21]
was also utilized to improve the step size for accelerating iteration times. The transducer’s equation
of impedance curve as a constraint in order to ensure the correctness of optimization parameters and their
correspondence with the miniature transducers’ physical conditions was used. In order to account for
measurement errors in the transducer’s displacement, the distribution function with different standard
deviations was used to simulate the measurement errors for verifying the results. The experiment
system that was employed in this study utilized a high-precision capacitive micro-displacement sensor
to measure the diaphragm displacement \(x(t)\). A high-precision electric current instrument was used
to measure the transducer’s electric current \(i(t)\). In the results and discussion sections, the numerical
simulation tests and experiments are both discussed in detail.

2. Mathematical Model

2.1. Transmission Equation

The suspension system of a miniature transducer comprises a surround and a diaphragm. The behaviors of these two parts are described by the mechanical mass, stiffness, and damping. The nonlinear vibration characteristics of the suspension and the magnetic system occur with the instantaneous excursion of voice-coil displacement from the mean position. To represent this nonlinear vibration characteristics in modeling, the nonlinear parameter \(K_m(x)\) as a form of the non-linear mechanical stiffness is used to describe the nonlinear vibration characteristics [8]. The parameters \(K_m(x)\) and \(R_m(x)\) indicate that the change in the value of the mechanical stiffness depends on the displacement \(x\), while \(L_e(x)\) represents the voice-coil inductance of the magnetic system, and \(B_l(x)\) represents the nonlinearity in the energy transfer between the electrical and mechanical domains. Figure 1a shows a schematic representation of the miniature transducer under large-signal conditions:

![Schematic representation of a miniature transducer](image_url)

**Figure 1.** Schematic representations of (a) A miniature transducer. (b) Diagram showing and key parameters, and (b) Diagram of the equivalent circuit.
The equivalent circuit of an electrical domain (Figure 1b) can be derived based on Kirchhoff’s voltage law (Equation (1)):

\[
L_e(x) \frac{d^2 i(t)}{dt^2} + \left[ \frac{dL_e(x)}{dx} \frac{dx(t)}{dt} + R_e \right] i(t) + B l(x) \frac{dx(t)}{dt} = e(t)
\]

where \( e(t) \) is the input voltage; \( i(t) \) is the voice coil current; and, \( x(t) \) is the voice coil displacement. Nonlinear parameters include voice coil inductance \( L_e(x) \) and the force factor \( B l(x) \). With regard to the mechanical domain, Newton’s second law of motion can be used to derive the current, as shown in the following equation:

\[
M_m \ddot{x}(t) + R_m(x) \frac{dx(t)}{dt} + K_m(x)x(t) = \left( B l(x) - \frac{dL_e(x)}{dx} \frac{i(t)}{2} \right) \dot{i}(t)
\]

where \( M_m \) is the mass of transducer diaphragm; \( R_m(x) \) is the damping coefficient of the suspension system; and, \( K_m(x) \) is the nonlinear coefficient of the stiffness of the suspension system. All nonlinear parameters, including \( K_m(x) \), \( R_m(x) \), \( B l(x) \), and \( L_e(x) \), are related to displacement \( x \). In the air load system model, the mass \( M_{rad} \) in Equation (2) includes the mechanical mass of the diaphragm and voice coil. The interaction of air load mass \( M_{rad} \) and resistance \( R_{rad} \) in acoustic radiations must be also considered [1]. Therefore, the air load in the mechanical and acoustic fields is given, as follows:

\[
M_{rad} \ddot{u}(t) = R_{rad} \left[ S_d \dot{x}(t) - u(t) \right]
\]

Under the initial conditions:

\[
x(0) = 0, \quad i(0) = 0, \quad u(0) = 0, \quad \text{and} \quad \frac{dx(t)}{dt} \bigg|_{t=0} = 0
\]

where \( S_d \) is the diaphragm area. The \( u(t) \) is the shunt volume velocity related to the acoustic radiation mass \( M_{rad} \) and the acoustic radiation resistance \( R_{rad} \) in Equation (4).

### 2.2. Nonlinear Parameter Fitting Equations

The nonlinear parameters \( R_m(x) \), \( B l(x) \), \( K_m(x) \), and \( L_e(x) \) describe variations along the axial direction of the displacement \( x \) of the membrane. According to refs. [12,22], these nonlinear parameters can be approximated based on the polynomial power series function. The polynomial function is shown in Equation (6):

\[
A(x) = \sum_{j=0}^{N} A_j x^j = A_0 + A_1 x + A_2 x^2 + \ldots + A_N x^N
\]

where \( j \) represents the index of summation; \( A_j \) in general may represent force factor, coefficient of mechanical stiffness, and voice coil inductance, depending on the nonlinear parameter under consideration; and, \( N \) is the upper bound of summation. The exponential approximation coefficients can also be used to fit the nonlinear parameters. The exponential fitting equation can be defined, as follows:

\[
A(x) = A_1 \exp \left( \frac{\pm(x - A_2)^2}{A_3^2} \right)
\]

where the coefficient \( A_1 \), \( A_2 \), and \( A_3 \) are the expected parameters of the nonlinear distribution and they can demonstrate the nonlinear parameters versus the displacement values. In this paper, the polynomial function was replaced with the exponential fitting function to reduce the measurement errors. As shown in Figure 2, when the polynomial equation was used to determine the nonlinear
parameters, the increased displacement of the nonlinear parameters could cause an error in the parameter curve.

![Graph showing comparison of power series curve in exponential and polynomial function.](image)

Figure 2. Comparison of the power series curve in exponential and polynomial function.

If the \( \mathbf{x}(0) \) parameter and initial condition are known (normally set to 0), the voice coil displacement \( \mathbf{x}(t) \) and electric current \( i(t) \) in Equations (1)–(5) are direct solutions. In contrast, for any time interval \( t \in (0, t_f) \), if the input voltage is \( v(t) \), the voice coil displacement is \( \mathbf{x}(t) \) and the voice coil current is \( i(t) \), then the solutions to the unknown coefficients in Equations (1)–(4) become optimal solutions. This study is aimed to determine all of the parameters described in the following section.

2.3. Calculation of Nonlinear Optimization Parameters

In order to obtain parameters by the proposed method, estimated and measured values of diaphragm displacement were used to define the target function \( J \).

\[
J(\mathbf{w}) = J_1(\mathbf{w}) + J_2(\mathbf{w}) = \int_0^{t_f} (\mathbf{x}(t; \mathbf{w}) - \mathbf{x}_{\text{mea}}(t))^2 dt + \mu \int_0^{t_f} (i(t; \mathbf{w}) - i_{\text{mea}}(t))^2 dt
\]

where the unknown vector \( \mathbf{w} = [M_m, R_m(x), Bl(x), K_m(x), L_e(x)] \) is the unknown nonlinear parameter that needs to be determined; \( \mathbf{x}(t; \mathbf{w}) \) is the estimated displacement; \( \mathbf{x}_{\text{mea}}(t) \) is the measured displacement using a precise displacement sensor; \( i(t; \mathbf{w}) \) is the estimated current; \( i_{\text{mea}}(t) \) is the measured current; and, \( \mu \) is the weight coefficient of the difference between \( J_1(\mathbf{w}) \) and \( J_2(\mathbf{w}) \). The equation shows that when the target function \( J(\mathbf{w}) \) reaches the minimum value, the estimated value \( \mathbf{x}(t) \) approaches the measured value \( \mathbf{x}_{\text{mea}}(t) \). Moreover, when the unknown coefficients of the vector \( \mathbf{w} \) approach its extreme value, a positive solution can be reached for \( \mathbf{w} \). The parameter \( \mathbf{w} \) can be adjusted, as follows:

\[
\mathbf{w}_{(n+1)} = \mathbf{w}_{(n)} - \beta_{(n)} \mathbf{P}_{(n)}
\]

where \( n \) represents the \( n \)th iteration; \( \beta_{(n)} \) represents the \( n \)th step; and \( \mathbf{P}_{(n)} \) is the \( n \)th direction with decreasing values of unknown parameter vector.
2.4. Broyden–Fletcher–Goldfarb–Shanno (BFGS) Algorithm

The BFGS method [20] is an unrestricted optimization method that has been recently acknowledged as the most effective algorithm for solving unrestricted nonlinear optimization problems by the iterative method. The BFGS method was used to adjust the \( P_n \) value in the following manner:

\[
P_n = -\left( \nabla J_n \right) A_n = -\left( \frac{\partial J_n}{\partial w} \right) A_n
\]

(10)

\[
A_n = A_{n-1} + E_{n-1}
\]

(11)

\[
E_n = \frac{1}{\Delta w_n^T \Delta g_n} \times \left[ \Delta w_n^T \Delta w_n \right] \left( 1 + \frac{(\Delta g_n)^T A_n (\Delta g_n)^T}{\Delta w_n \Delta g_n} \right) - A_n \Delta g_n (\Delta x_n)^T - \Delta x_n (\Delta g_n)^T A_n
\]

(12)

where \( A_0 = I \) is the identity matrix. \( \Delta w_n = w_n - w_{n-1} \) and \( \Delta g_n = g_n - g_{n-1} \) are the differences between iteration values and \( g_n = \nabla J(w_n) \) is the gradient function, which can be calculated, as follows:

\[
\nabla J(w_n) = \left( \frac{\partial J}{\partial w} \right)_{n} = \left[ \frac{\partial J}{\partial A_n} \right]_{N_n(x)} + \left[ \frac{\partial J}{\partial A_{N_n}} \right]_{N_n(x)} + \left[ \frac{\partial J}{\partial A_{N_n}} \right]_{N_n(x)} \frac{\partial t}{\partial A_n} \]

(13)

where \( \partial J/\partial w \) is the Jacobian matrix of the target function \( J(w) \), it can be obtained by using the forward difference method, as follows:

\[
\left( \frac{\partial J}{\partial w} \right)_{n} = \left( \frac{x(t; w + \Delta h) - x(t; w)}{\Delta h} + \frac{i(t; w + \Delta h) - i(t; w)}{\Delta h} \right)
\]

(14)

where \( \Delta h \) is set to a small number as \( 1 \times 10^{-8} \) to get the approximation of \( g_{n} \).

After determination of the search direction \( P_n \) and \( w \) minor deviation, a corresponding minor deviation \( \Delta x(t; w) \) is produced for displacement \( x(t; w) \). Thus, substituting \( \Delta x(t; w) \) and \( \Delta i(t; w) \) into Equation (8) leads:

\[
J(w)_{(n+1)} = \int_{t_0}^{t_f} \left[ x(t; w_{(n+1)}) - x_{\text{pred}}(t) \right]^2 dt + \mu \int_{t_0}^{t_f} \left[ i(t; w_{(n+1)}) - i_{\text{pred}}(t) \right]^2 dt
\]

(15)

When \( J(w)_{(n+1)} \) approaches 0, Equation (15) can be applied:

\[
\beta_{(n)} = \beta_{1(n)} + \beta_{2(n)} = \frac{\int_{t_0}^{t_f} (x(t; w) - x_{\text{pred}}(t)) \Delta x(t; w) dt}{\int_{t_0}^{t_f} \Delta x(t; w)^2 dt} + \mu \frac{\int_{t_0}^{t_f} (i(t; w) - i_{\text{pred}}(t)) \Delta i(t; w) dt}{\int_{t_0}^{t_f} \Delta i(t; w)^2 dt}
\]

(16)

where \( \Delta x(t; w) \) and \( \Delta i(t; w) \) can be used to conduct direct numerical differentiation of \( x_{(n+1)} - x_{(n)} / (\Delta k ||x||) \) and \( i_{(n+1)} - i_{(n)} / (\Delta k ||i||) \), respectively. In this study, \( \Delta k \) was the extreme value \( 1 \times 10^{-8} \), which is set for displacement \( x \).

2.5. Brent’s Algorithm

As the target function approaches the minimum value with each iteration, deviations could occur with respect to the step value \( \beta_{(n)} \) that was obtained from Equation (16). In order to obtain the optimal step values in the iteration direction, Brent’s algorithm [21] was used to derive the approximate optimal value \( \beta_{(n)} \). With regard to the numerical analysis, Brent’s method is a complex but widely used root-finding algorithm that combines dichotomy, the secant method, and inverse
quadratic interpolation. In Brent’s algorithm, the new value $\beta_{(n)}$ can be obtained through the following iteration process:

$$\beta_{(n),i+1} = b - \frac{1}{2} \frac{(b-a)^2 |J_b - J_c| + (b-c)^2 |J_c - J_A|}{(b-a)(b-c)}$$  (17a)

where

$$a = 0.001 \beta_{(n),i}, \quad b = \frac{1}{2} \beta_{(n),i}, \quad c = \beta_{(n),i}$$  (17b)

$$J_A = J(w(n) - aP_{(n)}), \quad J_B = J(w(n) - bP_{(n)}), \quad J_C = J(w(n) - cP_{(n)})$$  (18)

where $i$ is the iteration index; $a$, $b$, and $c$ form a parabolic target function; $b$ is the initial center point obtained by halving $\beta_{(n)}$ in Equation (16); and, $[a, c]$ is the established time interval. With each iteration the interpolation of the parabolic curve can reach optimal $\beta_{(n),i}$ under two conditions:

1. The selected $\beta_{(n),i}$ value must be within the $[a, c]$ interval.
2. The variation approaching the optimum value cannot exceed the previous variation by more than half, which means that the following inequality must be met: $|\beta_{(n),i} - \beta_{(n),i-1}| < 1/2 |\beta_{(n),i-1} - \beta_{(n),i-2}|$.

If the two conditions cannot be satisfied, then the golden section search method must be applied in iteration. The iteration method always requires a stop criterion, which is given, as follows:

$$\frac{c - a}{2} < 2 |\epsilon_{ef}\beta_{(n),i} - |\beta_{(n),i} - \frac{c - a}{2}$$  (19)

When Equation (19) is established, iteration steps are no longer conducted.

2.6. Constraint Equations

The constraint equation that is proposed in this study is the definite method that restricts $M_m$, $K_m(x)$, $B_l(x)$, and $R_m(x)$. It must be noted that the relationship between these parameters can be formed by T/S parameters.

$$\omega_0 = \sqrt{\frac{K_m(x(0))}{M_m}}$$  (20)

$$Z_T - R_e = \frac{B_l(x(0))^2}{R_m(x(0))}$$  (21)

where $\omega_0$ is related to the resonant angular frequency of linear part $K_m(x(0))$ and the $M_m$; $Z_T$ is restricted to the resistance value during resonance ($f / f_0 = 1$); and, $x(0)$ is the linear term that does not change with the displacement.

Equations (20) and (21) can be integrated in the Equation (3), as follows:

$$\left(B_l(x) + \frac{dL_r(x)}{dx} \frac{1}{2} \right) i(t) = \left( \frac{K_m^2(x(0))}{\omega_0^2} + M_{rad}\sqrt{\omega_0} \right) x(t) + R_m(x)x(t)$$  (22)

and

$$R_m(x) = \frac{B_l((x(0))^2}{Z_T - R_e} \exp \left( \frac{sign(x - R_m(x(1))^2}{R_m(x(2))^2} \right)$$  (23)

As seen from the observations above, different $Z_T$, $R$, $B_l(x(0))$, and $K_m(x(0))$ values can directly affect $M_m$ and $R_m(x(0))$. In each iteration, $Z_T$ can serve as the constraint for parameter changes. The $R_e$ decreases at higher frequencies, whereas $L_r$ increases at higher frequencies. Thus, the excitation signals must cover low and high frequencies. In this study, constraint equations were used in the BFGS–Brent method to compare the estimation results.
2.7. Computational Algorithm

The computational procedure of the presented method may be summarized, as follows,

**Step 1** Let the search index \( n = 0 \), and arbitrarily choose a set of initial values of a vector as \( w(0) \).

**Step 2** Substitute \( w(n) \) into transmission Equations (1)–(4) using numerical solver as finite difference method to obtain the values of \( x(t;w) \) and \( i(t;w) \), and use Equation (8) to obtain \( J(w) \).

**Step 3** Solve Equations (13) and (14) for \( g(n) \) and substitute it into Equation (12) to obtain \( E(n) \). Let \( A(0) = I \) when \( k = 0 \); otherwise, substitute \( E(n) \) into Equation (11) to obtain \( A(n) \). Then, substitute \( g(n) \) and \( A(n) \) into Equation (10) to get search direction \( P(n) \).

**Step 4** For the step length, the two methods are proposed. The first is to solve Equation (16) to obtain step length \( \beta(n) \). The second is to use the Brent’s method (Equation (17a)), which is described in Section 2.5 to get \( \beta(n) \).

**Step 5** After obtaining \( P(n) \) and \( \beta(n) \), the new \( w(n+1) \) can be obtained from Equation (9). If constraint equations in Section 2.6 are applied, substitute \( \omega_0, Z_T, \) and \( w(n+1) \) into Equations (20)–(23) to make sure \( w(n+1) \) are matching the constraints, if not, update the \( w(n+1) \) from constraint Equations (20)–(23).

**Step 6** Set the search iteration to \( n = n + 1 \) and determine whether \( J(w) \) is smaller than the preset tolerance \( \epsilon \left( \leq 1 \times 10^{-7} \right) \) of convergence criteria or the specified number of iterations. If the constraint of the convergence criteria is satisfied, end the iteration process; otherwise, start from Step 2 again.

3. Simulation Results and Empirical Results Verifications

3.1. Simulation Results

In the simulation, the maximum input voltage \( V_p \) was set to 1000 mV. The directly measured displacement \( x_{\text{mea}}(t) \) and current \( i_{\text{mea}}(t) \) were used to conduct analysis in the experiment case. The values of the input parameters and units are given in Table 1. The fitting equation of the nonlinear parameters was defined as Equation (7). The values initial guesses of parameters were initially inferred based on \( w \). In this case study, the initial guesses of parameters can be randomly done in the suitable range. To explain the suitable range of determined results, Table 2 examines the influence of three sets of initial guesses on optimization convergence. All of initial guesses are generated with random numbers. The range of the initial guesses is assumed around 10 or 1/100 times the exact parameters from Table 1. With regard to the correctness and calculation efficiency of the method proposed in this study, the following random voltage \( V_p \) and angular frequency \( \omega_f \) dependent sinus signal was used:

\[
e(t_n) = \text{Random}(V_p) \cdot \sin \left( \text{Random}(\omega_f) t_n \right),
\]

where \( t_n = 0 \sim t_N \) and \( \omega_f = 50 \text{ Hz to 10,000 Hz} \).

</table>
The reason for a conventional distortion measurement of displacement and current is because the harmonic distortions usually occur in the low frequencies range (as 10 Hz to 300 Hz) caused by the nonlinear force factor \( Bl(x) \), stiffness \( K_m(x) \) and damping factor \( R_m(x) \). However, the Inductance \( L_e(x) \) (magnetic AC-field varies with coil position) increases the impedance at higher frequencies (after 500 Hz). Therefore, the distortions related to the nonlinear parameters should be measured by exciting the miniature transducer with a broadband signal, such as pseudo-random noise and by applying the proposed method to the input and output signal.

The efficiency and feasibility of the proposed method are demonstrated using simulation tests. First, a set of exact parameters is given. Second, the numerical solver is used to solve the exact equations. Subsequently, the above computational procedure is used to obtain the predict results. As a result in Table 3, the objective function in each case is smaller than 1 \( \times 10^{-3} \), it indicates that accurate parameters can be obtained by the proposed method. It is observed that the iteration numbers would be increased if the initial guesses are not close to the exact parameters. Therefore, it can be determined that the assumed initial guess value is appropriate by confirming the number of iterations and the convergence function.

Note: \( R_e \) which is measured by electrical meter.

Following the nonlinear optimization procedure that was proposed in the previous section, the nonlinear parameters, impedance curves, displacement \( x(t) \), and current \( i(t) \) were obtained using the proposed algorithms BFGS, BFGS-Brent, and BFGS with constraints that were subsequently compared. A comparison of the positive and estimated values is shown in Figure 3a–d. The results for \( Bl(x), K_m(x), L_e(x), \) and \( R_m(x) \) indicated high consistency between the predicted and exact curves that were obtained using the method proposed in this study.

Note: \( M_m \) is the linear parameter which do not effect by displacement.
where $\sigma$ is a random number which is substituted into Equation (25) to obtain $x_{\text{sim}}(t)$, which has a slight deviation from $x_{\text{mea}}(t)$. The different values of $\sigma$ may be considered to simulate the potential range of measurement error. Figure 4 shows the comparison of the displacement values with different standard deviations ($\sigma = 0.01, 0.05, 0.11, 0.15$).

As a result of nonlinear parameters that were obtained from Figures 5–7, it can be observed that if $\sigma$ is greater than 0.05, then the amplitudes and phase are complex and varying. When $\sigma = 0.1$ and 0.15, different nonlinear parameter curves are observed. Simulated measurement errors ($\sigma = 0.01, 0.05, 0.15$) of the nonlinear parameters are shown in Figures 5–7, respectively. The figures show uniformity of the curves at $\sigma = 0.01$ and $\sigma = 0.05$. However, curves of the $B_l(x)$ at $\sigma = 0.01$ and $\sigma = 0.05$ clearly differ from the exact curve at $\sigma = 0.0$ (Figures 5a, 6a and 7a). It should be noted that the difference is mainly
presented in the central parts and not at the extremes of the curves. Moreover, large variation was produced in the $\sigma = 0.15$ curve and the exact curve, approaching lower $Bl(x)$ values.

Figure 4. Comparison of the displacement $x_{\text{sim}}(t)$ at different measurement errors.

Figure 5. Effect of measurement error $\sigma = 0.01$ on nonlinear parameters, (a) $Bl(x)$, (b) $K_m(x)$, (c) $L_e(x)$, and (d) $R_m(x)$. 
Figure 6. Effect of measurement error $\sigma = 0.05\sigma$ on nonlinear parameters, (a) $B_l(x)$, (b) $K_m(x)$, (c) $L_e(x)$, and (d) $R_m(x)$.

Figure 7. Cont.
When the measurement error was small, the changes in the curve were considerable. The results when \( \sigma \) were observed in the predicted parameters when the simulated measurement error was greater than \( \sigma \). The comparison of impedance curves in Figure 8a–c show that, unlike BFGS with constraint, the BFGS and BFGS-Brent methods failed to fit the exact curve. However, as the simulated measurement error is increased, the three methods could not accurately match the precise values of the impedance. When the measurement error was small, the changes in the curve were considerable. The results indicated that, in the case of large measurement error, the proposed method could not accurately determine the nonlinear parameters.

With reference to the \( K_m(x) \) and \( R_m(x) \) curves (Figures 5b,d, 6b,d and 7b,d), the \( \sigma = 0.01 \) and \( \sigma = 0.05 \) simulated measurement error in displacement curves (as shown in Figure 4) were almost identical, however more evident deviation have been observed in the \( \sigma = 0.15 \) curve. An error deviation mainly occurred in the central parts of the curves rather than the extremes of the \( K_m(x) \) and \( R_m(x) \) curves. The \( \sigma = 0.05 \) and \( \sigma = 0.15 \) error curves overlapped in the extreme parts of the curves and started deviating in the central part of the higher side of \( K_m(x) \). A clear difference was observed in the \( L_e(x) \) curve at the error \( \sigma \geq 0.05 \) (Figures 6c and 7c).

The results showed that when the standard deviation was lower than the simulated measurement error of \( \sigma = 0.01 \), all of the nonlinear parameters matched the positive curve. The greater changes were observed in the predicted parameters when the simulated measurement error was greater than \( \sigma = 0.05 \). The parameters only roughly matched the trend of the positive curve, particularly in the calculation of \( Bl(x) \), \( K_m(x) \), and \( R_m(x) \). The \( L_e(x) \) calculation curve showed that the predicted trend did not match the \( L_e(x) \) predicted curve. As indicated by the results that are shown in Figures 5–7, when \( \sigma \geq 0.05 \), the estimated nonlinear curves cannot fit the original curves accurately; however, the results remained within the acceptable range when \( \sigma < 0.05 \).

The comparison of impedance curves in Figure 8a–c show that, unlike BFGS with constraint, the BFGS and BFGS-Brent methods failed to fit the exact curve. However, as the simulated measurement error is increased, the three methods could not accurately match the precise values of the impedance. When the measurement error was small, the changes in the curve were considerable. The results indicated that, in the case of large measurement error, the proposed method could not accurately determine the nonlinear parameters.
were used to measure the displacement of the miniature transducer diaphragm. In the measurement
analyses and calculations. Figure 9 shows the interface and measurement procedure of the capacitive
transducer diaphragm using a signal acquisition card. The signals were transmitted to a computer
measure and record signals that are based on the voltage values between the sensor and miniature
error is increased, the three methods could not accurately match the precise values of the impedance.
This study constructed a measurement system with a non-contact capacitive sensor that could
measure the changes in the displacement of the miniature transducer diaphragm, i.e., displacement
Le
\( x \) in Equation (1). The high-precision capacitance displacement nano-sensor manufactured by the
US company LION Precision [23] was used in the system; the sampling rate was according to National
Instruments NI-DAQ 6251 (set to 48,000 Hz) [24]. The random sinus signals (Equation (24)) were used
to actuate the transducer; the displacement signals were captured and transmitted to the computer for
measurements. Large signals were used because the nonlinear characteristics that were produced in the metal
displacement x(t) in Equation (1). The high-precision capacitance displacement nano-sensor manufactured by the
US company LION Precision [23] was used in the system; the sampling rate was according to National
Instruments NI-DAQ 6251 (set to 48,000 Hz) [24]. The random sinus signals (Equation (24)) were used
to actuate the transducer; the displacement signals were captured and transmitted to the computer for
analyses and calculations. Figure 9 shows the interface and measurement procedure of the capacitive
sensor system that is proposed in this study. With regard to the verification of the method proposed in
this study, a capacitive displacement system and laser vibrometry displacement measurement system
were used to measure the displacement of the miniature transducer diaphragm. In the measurement
process, a power amplifier was used to generate 1.4 \( V_{rms} \) random sinus signals. Large signals were used
because the nonlinear characteristics that were produced in the metal diaphragm of the transducer
need to be captured. The excitation signals were recorded using a voltage sensor. The voice coil
current \( i_{meas}(t) \) was measured using a current sensor and the displacement \( x_{meas}(t) \) was measured using
a capacitance displacement sensor. Laser beams of the laser displacement measurement system were
concentrated at the center of the transducer diaphragm for measurements.

3.3. Discussion of Empirical Results

Figure 10 compares the displacements (direct solution) that were obtained after the integration of the linear parameters (traditional parameter measurement method [1,3]) and the displacements measured using the capacitance displacement system and laser displacement measurement system. The simulation result is the direct solution that was obtained by substituting the nonlinear parameters identified by the proposed optimization method (Section 2.3). As seen from Figure 10, the laser displacement measurement system deviated from the direct solution, whereas the capacitance displacement system approached the direct solution. In this case, the displacement measurement errors caused by membrane vibration in a miniature transducer with a metal membrane during laser measurements may be due to optical refraction. Hence, it is established that the capacitance displacement system is more applicable and appropriate for the transmission equation calculations (Section 2.1) related to miniature transducers.

Figure 10. Comparison of displacement data simulated by the model and displacement measured by using the capacitance and laser displacement measurement systems.
Figure 11a–e compare the results of measurement by the capacitance system and laser displacement measurement system. The results of the proposed system were found to be different from those of the laser displacement measurement system, which could be due to the repeated fitting results of the latter. The changes in nonlinear parameters could be caused by the temperature and long operation of the miniature transducer. However, the impedance curve in Figure 12 shows that all the theoretical solutions fit resonance frequency and peak values. The impedance curve in Figure 12 shows that due to $R_m(x)$ deviation, BFGS influenced the resonance frequency peak values of the impedance curve. As shown in Figure 13, all of the measurement curves that were fitted using different methods were good, indicating that the method proposed in this study had certain accuracy for the miniature transducer response $R_m(v)$ measured by the laser displacement measurement system, which made it impossible to compare the $R_m(x)$ solutions within the same figure. Figure 13 also indicates that the BFGS with constraint method gives more fit to the measurement result, which is probably due to the constraints of the parameters. Hence, BFGS with constraint method is a more realistic and stable method; however, the results of the three methods were similar. The illustration of nonlinear issues can refer to [5], the nonlinear curves as $B_l(x)$, $K_m(x)$, and $R_m(x)$ in Figure 11 are almost symmetric. The surround that was made of the plastic and metal material causes a minor asymmetry. The result is a benefit to addressing the problem and adjusting the design of miniature transducers to obtain the minimal distortions.

**Figure 11. Cont.**
Figure 11. Comparison of nonlinear parameter curves obtained using different methods and laser displacement measurement system. (a) $B_l(x)$, (b) $K_m(x)$, (c) $L_e(x)$. (Note: Laser dependent on right scale), (d) $R_m(x)$, and (e) $R_m(v)$. (Note: $R_m(v)$ was used in measurement of $R_m(x)$ using the laser displacement measurement system; thus, another comparison is made).

Figure 12. Comparison of impedance curves obtained using different methods and the laser displacement measurement system.
The results indicated that, when \( \sigma \geq 0.05 \), more accurate nonlinear parameter curves were obtained. Conversely, when \( \sigma < 0.05 \), deviations were observed in the obtained nonlinear curves; however, the numerical value of results remained within the acceptable range. The results indicated that a better search step was achieved through the integration of the two methods; iteration efficiency was accelerated, optimal parameter calculations were reduced, and all nonlinear parameters could be accurately predicted. With regard to empirical verification, the use of different methods was able to better fit the theoretical parameter calculations when there were fewer measurement errors.

To sum up the advantages that are described above, the capacitance displacement measurement system proposed in this study can be applied in electroacoustic measurements. The method proposed in this study can be widely applied in the development of electroacoustic transducers, as it can help in solving engineering issues and improve transducer designs.

**Author Contributions:** Y.-T.T. and Y.-C.J. defined the research theme included the parts of conceptualization, methodology, validation. Y.-T.T. developed the code and provided experimental resources. Y.-C.J. did the laboratory experiments, data curation and original draft preparation in Chinese. P.S.J. interpreted the results. Y.-T.T. wrote this manuscript, and did the final review and editing with P.S.J. Everyone interacted with each other and made corresponding modifications in their domain.

**Funding:** The authors would like to thank the Ministry of Science and Technology of Taiwan for financial support under Contract Nos. MOST 105-2511-S-035-012-MY3, MOST 106-2221-E-035-051-, 107-2218-E-035-016- and MOST107-2221-E-035-061-.
