Abstract: The performance of plasma-modified Pt/CeO$_2$ for toluene catalytic oxidation was investigated. Pt/CeO$_2$ nanorods were prepared by wet impregnation and were modified by thermal (PC-T), plasma (PC-P), and combined (PC-TP and PC-PT) treatments. The modified catalysts were characterized by TEM (transmission electron microscope), BET (Brunauer-Emmett-Teller), H$_2$-TPR, O$_2$-TPD, XPS, UV-Raman, and OSC tests. The significant variation of the surface morphologies and surface oxygen defects could have contributed to the modification of the Pt/CeO$_2$ catalysts via the plasma treatment. It was found that plasma could promote the surface interaction between Pt and CeO$_2$, resulting in the thermal stability of the catalyst. The Pt-Ce interaction was also conducive to an increase in the number of oxygen vacancies. Furthermore, PC-PT and PC-TP showed a significant difference in oxygen vacancy concentrations and catalytic activities, which illustrated that the treatment sequence (plasma and thermal treatment) affected the performance of Pt/CeO$_2$. The PC-PT sample showed the highest catalytic activity with $T_{100}$ at 205 °C. This work thus demonstrates that plasma in combined treatment sequences could assist surface interactions of catalysts for enhanced toluene catalytic oxidation.

Keywords: non-thermal plasma; Pt/CeO$_2$; oxygen vacancies; treatment sequence

1. Introduction

Volatile organic compounds (VOCs) are high-risk contaminants, which can cause a significant threat to the nervous system and the environment [1,2]. Toluene is a representative VOC, which is of high toxicity and very difficult to naturally degrade. In the past few years, the use of noble metals (Pt, Au, Pd) and redox supports (CeO$_2$, Co$_3$O$_4$, ZrO$_2$) [3–6] to improve toluene oxidation has been prevalent. In particular, Pt-based materials have been widely adopted for toluene oxidation because of their excellent toluene dissociative adsorption abilities [7]. Meanwhile, the CeO$_2$ redox support has attracted considerable attention due to its high oxygen storage ability. During the traditional preparation of these catalysts, calcination is employed to activate the catalyst, but they are at risk of sintering at high temperatures. To avoid this risk during Pt/CeO$_2$ activation, non-thermal plasma has been proposed as an alternative technique.

Non-thermal plasma (NTP) is a promising technology for catalyst surface treatment, which could alter the morphology and chemical states of a catalyst, create more defects on the catalyst surface, and
activate the catalyst in facile reaction conditions (fast response at room temperature). It could also improve the activity and thermal stability of the catalyst [8,9]. Di et al. [10] reported that the Pd/P25 catalyst reducing by plasma treatment had a smaller Pd particle size and showed a better activity for CO oxidation. Gulyaev et al. [11] prepared Pd/CeO$_x$ by plasma synthesis and found an increase of Pd dispersion and turnover frequency (TOF) after discharge. Notably, previous discussions of catalyst modification during discharge mainly concentrated on the surface morphology changes, dispersion of active metals, and the reduction extent of the catalysts, but its effect on surface defects such as oxygen vacancies should not be neglected. Ye et al. [12] introduced plasma and thermal annealing to create various defects on MoS$_2$ to promote the hydrogen evolution reaction. Xu et al. [13] employed plasma to engrave Co$_3$O$_4$ nanosheets, which produced more oxygen vacancies on the Co$_3$O$_4$ surface after discharge, and the activity improvement was attributed to a larger number of exposed active defects. Although plasma-induced catalyst surface defects have gained research attention, there have been few studies on the effect of plasma on CeO$_2$ surfaces. Furthermore, the more efficient use of plasma should be studied. Qi et al. [14] used a single plasma to reduce Pd species on activated carbon at low temperatures to avoid sintering, but the reduction of PdO$_x$ was insufficient. Lee et al. [15] claimed that sintering is an issue for catalysts at high temperatures. Hence, single methods (plasma or thermal) have not met the demands for catalyst modification. Thus, a combination of plasma and thermal methods may address these issues. Laura et al. [16] attempted to modify Pt catalysts by using a combination of plasma and thermal reduction and suggested that catalysts prepared via this method exhibited higher activities in the water-gas shift reaction than catalysts treated by only single plasma or calcination. Thus, the combination of plasma and thermal treatment is prominent for active catalyst modification. Currently, the synergetic effect of combining plasma and thermal treatment is still unclear, and the role of plasma in combined treatment also should be clarified.

In this study, Pt loaded on CeO$_2$ nanorods was employed as a catalyst, and the catalytic performances of Pt/CeO$_2$ with plasma and/or thermal treatments were compared. To investigate the effects of plasma on physical/chemical changes of the catalyst, X-ray diffraction (XRD), high-resolution transmission electron microscopy (HRTEM), X-ray photoelectron spectroscopy (XPS), UV-Raman, H$_2$-temperature programmed reduction (H$_2$-TPR), O$_2$-temperature programmed desorption (O$_2$-TPD), and oxygen storage capacity (OSC) tests were used. Furthermore, the TOFs based on Pt particles and oxygen vacancies were calculated. Through these characterizations, the effect of combining catalyst treatments in various sequences was uncovered.

2. Results

The catalytic oxidation of toluene was evaluated. As shown in Figure 1, the catalytic activities of the samples were in the following order: PC-PT > PC-TP > PC-P > PC-T > PC-U. Compared to pure CeO$_2$ whose T$_{100}$ had reached 328 °C, the catalytic activities of Pt/CeO$_2$ was improved. The lowest T$_{100}$ and T$_{50}$ were found for PC-PT at 205 °C and 167 °C, respectively, while the T$_{100}$ of PC-TP was 236 °C, 30 °C higher than that of PC-PT. Therefore, the treatment sequence in combined treatment could affect the catalytic activity. Moreover, Arrhenius plots were used to further compare the chemical kinetic activities of the samples, as shown in Figure 2 and Table 1. The Arrhenius plots were obtained when the toluene oxidation conversion was below 10%, and a linear correlation was found. As shown in Table 1, the activation energy (E$_a$) values for PC-PT, PC-TP, PC-P, PC-T, and PC-U are 74.5, 83.1, 89.2, 102.6, and 116.8 kJ mol$^{-1}$. The E$_a$ values of PC-PT and PC-TP are lower, indicating an easier activation of toluene oxidation.
Evidently, the catalysts treated with plasma and thermal processes exhibited better catalytic activities, which deserves further discussion. Generally, a Pt particle is regarded as an active site of Pt-based materials. Greater Pt dispersion can expose more Pt atoms, which is associated with active toluene oxidation due to the excellent toluene adsorption [17]. To investigate this effect, TOF$_{\text{Pt}}$ values based on Pt dispersion were calculated. As listed in Table 1, the TOF$_{\text{Pt}}$ values were 7.9 × 10$^{-3}$, 7.4 × 10$^{-3}$, 6.2 × 10$^{-3}$, 6.1 × 10$^{-3}$, and 3.1 × 10$^{-3}$ s$^{-1}$ for PC-PT, PC-TP, PC-P, PC-T, and PC-U, respectively. Compared to the samples without plasma modification (PC-T and PC-U), the catalytic activities of the plasma-treated samples (PC-PT and PC-TP) and TOF$_{\text{Pt}}$ values increased. Since TOF$_{\text{Pt}}$ was the turnover frequencies based on the Pt particles, and a positive correlation exists between the TOF$_{\text{Pt}}$ value and the catalytic activity, it was inferred that Pt particles were active sites. In addition, Asgari et al. [18] reported that oxygen vacancies played a vital role in the catalytic oxidation by controlling the consumption and supplementation of surface activated oxygen. TOF$_{\text{ov}}$ values were also calculated (Table 1) as follows: PC-PT (3.6 × 10$^{-4}$ s$^{-1}$), PC-TP (3.4 × 10$^{-4}$ s$^{-1}$), PC-P

Figure 1. Conversion of toluene over catalysts with various treatment.

Catalyst amount: 200 mg; Toluene concentration: 200 ppm; gas flow: 100 ml min$^{-1}$.

Figure 2. Arrhenius plots for the oxidation of toluene over different Pt/CeO$_2$ catalysts.
The similar trends between the catalytic activities and TOF<sup>ov</sup> values confirmed that oxygen vacancies were also crucial active sites that determined the performances of the samples.

<sup>1</sup> The TOF values were calculated at 150 °C.

The specific surface areas (S<sub>BET</sub>) of the samples are shown in Table 2. The S<sub>BET</sub> of PC-PT was increased by nearly 10 m<sup>2</sup> g<sup>−1</sup> as compared to that of PC-T, which indicated that catalysts’ morphologies were modified by the plasma. This might be ascribed to the fact that plasma-excited species etched the catalyst surface [19] and some of the CeO<sub>2</sub> nanorods were cracked and became shorter, exposing more of the catalysts’ surface area. The decrease of S<sub>BET</sub> was attributed to sintering of the catalysts at high temperatures. However, the slight decreases of S<sub>BET</sub> from PC-P to PC-PT/PC-TP suggested that plasma treatment was conducive to inhibiting the sintering of catalyst. The Pt loading amounts of the samples ranged from 0.79–0.81 wt %, as shown in Table 2.

<sup>1</sup> Determined by ICP-OES. <sup>2</sup> Determined by TEM. <sup>3</sup> Determined by CO-chemisorption. <sup>4</sup> Determined by N<sub>2</sub> isotherm. <sup>5</sup> Determined by XRD.

TEM images of the catalysts are presented in Figure 3. The images of the samples showed the spacing of 0.32 nm for the (111) crystal planes of CeO<sub>2</sub> and identical Pt lattices with a Pt (111) interplanar distance of 0.23 nm. Samples were rod-shaped, as expected, but partial cracking occurred on the CeO<sub>2</sub> nanorods modified by plasma. Thus, the plasma treatment yielded shorter CeO<sub>2</sub> nanorods. The Pt particle sizes were determined from the images, and the results are listed in Table 1. For PC-P, PC-TP, and PC-PT, the mean Pt particle sizes were 2.3 nm, 2.4 nm, and 2.5 nm, respectively, but the size of PC-T was 3.2 nm. Compared to the Pt particle size of PC-T, PC-P showed a decreased Pt particle size, and the particle sizes of PC-TP and PC-PT were also obviously smaller than that of PC-T. This was attributed to the etching effect of the plasma: Pt particles that aggregated into clusters were split by the plasma in the discharge area and dispersed uniformly on the catalyst surface. The Pt particle sizes estimated by CO-chemisorption were as follows: PC-T (3.6 nm), PC-P (2.6 nm), PC-TP (2.8 nm), and PC-PT (2.7 nm). These calculated sizes were larger than those determined from the TEM images, which is consistent with previous reports [20,21]. The small differences between the Pt particle sizes obtained by TEM and CO-chemisorption proved the accuracy of the TEM test. The corresponding platinum particle dispersions are also listed in Table 2. The Pt dispersion for PC-PT was 46.9%, followed by PC-TP (45.0%). Notably, the PC-PT and PC-TP samples had similar Pt dispersions, indicating that the
different treatment sequences had little effect on the particle size. The variety of catalytic activities between PC-PT and PC-TP should not only be attributed to Pt dispersion.

Figure 3. TEM image images of samples and size distribution of Pt particles on CeO$_2$ support.

The XRD patterns of the five samples are shown in Figure 4. The diffraction patterns of all the samples exhibited face-centered cubic fluorite structures (JCPDS card No. 34-0394) [22]. The deficiency of the diffraction peak of Pt metal (39.8°) was due to the high dispersion or low loading of Pt. The average crystallite size of each material was calculated from the Scherrer equation based on the full width at half maximum (FWHM) of the CeO$_2$ (111) plane, and the results are displayed in Table 2. PC-P showed a decrease of the mean crystal size compared to that of PC-U, suggesting that the plasma discharge had a shrinkage effect on the catalyst morphology. Some studies found that as the crystal size decreased with a lower Ce–O symmetry, the number of surface oxygen sites/oxygen vacancies in the CeO$_2$ sample increased [23]. In addition, thermal treatment at high temperatures could induce catalyst sintering [24], as is evidenced by the difference in the crystal sizes between PC-U and PC-T. However, compared to the remarkable increase of the crystal size from PC-U to PC-T, the slight change from PC-U to PC-PT suggested that the plasma might inhibit the catalyst sintering [25,26]. Moreover,
Farmer et al. [27] suggested that sintering was strongly affected by the metal-support interactions. Yang et al. [28] proved that plasma could enhance the interface reaction between the support and metal, and stabilize the plasma-activated Pt catalyst in sintering tests. Therefore, the sintering inhibition of PC-PT was likely due to Pt-Ce interface reactions, as Pt was inserted into CeO$_2$, and made the crystal structure more stable at high temperatures [15]. The crystal sizes of PC-TP (8.0 nm) and PC-PT (7.3 nm) indicated that different treatment sequences could result in changes of the catalyst structure, and thus, the thermal stability varied.

![Figure 4. XRD pattern of different Pt/CeO$_2$ samples.](image)

XPS analysis was employed to estimate the surface composition of the catalysts, and the results are shown in Figure 5 and Table 3. Figure 5A shows the spectra of the Ce species, which were fit with eight peaks, corresponding to the pairs of spin-orbit doublets. Ce 3d$_{5/2}$ and Ce 3d$_{3/2}$ spin–orbit components were denoted as U and V, respectively. Based on previous reports, three pairs of peaks, V (881.9 eV), U (899.3 eV); V" (888.5 eV), U" (905.9 eV); and V‴ (897.6 eV), U‴ (915.0 eV), were ascribed to Ce$^{4+}$ [29]. The peaks V′ (884.2 eV) and U′ (901.6 eV) were assigned to Ce$^{3+}$. The data in Table 3 shows that the Ce$^{3+}$ ratios of the combined-treated sample PC-TP (27.07%) and PC-PT (30.30%) were higher than that of the single-treated samples PC-T (22.35%). Since the relative contents of Ce$^{3+}$ were regarded as an indicators of oxygen vacancies on the CeO$_2$ surfaces, it was inferred that the samples modified by combined treatments obtained a greater number of oxygen vacancies than those modified by a single method. Moreover, when PC-U was compared with PC-P, the Ce$^{3+}$ ratio increased from 20.44% to 26.44%, and the Ce$^{3+}$ ratio of PC-PT had a further increase to 30.30%. The increased Ce$^{3+}$ ratio indicated that the catalyst oxygen vacancies increased stepwise due to the plasma plus thermal treatments.

The O1s spectra are shown in Figure 5B. The O1s spectra were deconvoluted into two peaks: peaks in the 532.1–532.4 eV range were assigned to surface oxygen (O$_{ads}$), and peaks in the 529.6–529.9 eV range were assigned to lattice oxygen (O$_{latt}$) [30]. The relative proportions of O$_{ads}$ could reflect the concentration of surface oxygen species over the catalyst. As shown in Table 3, O$_{ads}$ ratio increased in the following order: PC-U, 51.07%; PC-T, 53.69%; PC-P, 63.78%; PC-TP, 64.20%; PC-PT, 70.11%. The relative ratios of O$_{ads}$ for plasma-treated samples ranged from 63.78% to 70.11% when the ratios of PC-T and PC-U were less than 55%. Hence, the concentration of surface active oxygen was increased through plasma treatment. Furthermore, the O$_{ads}$ proportion increased from 63.78% (PC-P) to 70.11% (PC-PT) due to the combined treatment, which might explain the better catalytic activity of PC-PT.
than PC-P, because more surface-active oxygen species on the catalyst would enhance its catalytic performance for toluene oxidation [31].

The Pt 4f spectra, comprising Pt 4f\(_{7/2}\) and Pt 4f\(_{5/2}\), are shown in Figure 5C. Pt was present mainly in metallic states Pt\(^0\) and platinum oxide Pt\(^{\delta+}\) (Pt\(^{2+}\), Pt\(^{4+}\)). The peaks of the Pt\(^0\) species appeared at 70.6 and 73.9 eV, the peaks of Pt\(^{2+}\) appeared at 72.0 and 75.2 eV, and the peaks of Pt\(^{4+}\) appeared at 73.7 eV and 77.0 eV. The content of Pt\(^0\) in PC-T, PC-TP, and PC-PT were greater than 75%, while it was only 62.5% in PC-P. It was confirmed that Pt species of the PC-P sample contained lower amounts of Pt\(^0\). Hence, it was necessary to employ a combined modification method to activate the catalyst, combining thermal treatment with H\(_2\) as a supplement to plasma reduction. The relative surface platinum concentrations of the various catalysts might imply the inward diffusion of Pt [32]. The low Pt/Ce ratios shown in Table 3 for PC-PT, PC-TP, and PC-P were attributed to the incorporation of Pt into the CeO\(_2\) surface layer, which enhanced the interaction between Pt and CeO\(_2\). However, the significantly lower ratio in PC-T was due to Pt incorporation into the CeO\(_2\) bulk lattice as a result of catalyst sintering [33]. Therefore, when the Pt/Ce ratios of PC-PT and PC-TP were compared with that of PC-T, it was indicated that the plasma in combined treatments likely inhibited sintering and promoted metal-support interactions.

\(\text{H}_2\)-TPR was employed to analyze the reducibilities of the samples with various treatments. As shown in Figure 6, the profile of CeO\(_2\) only consisted of one wide peak, and the peak temperature ranged from 250 °C to 500 °C, which was assigned to the reduction of oxygen species on the surface and subsurface of CeO\(_2\). After the impregnation of Pt on CeO\(_2\), two reduction peaks appeared at around 100 and 400 °C. The first peak indicated the reduction of PtO\(_x\) or ceria oxygen adjacent to Pt species, and the second peak is assigned to ceria oxygen far from the Pt [34]. Compared to PC-U, the peak positions of the samples with plasma treatment shifted to lower temperatures significantly, with the peak
temperatures of PC-P, PC-TP, and PC-PT shifted from 138 °C (PC-U) to 103, 101, and 94 °C, respectively. Higher temperature peaks of around 400 °C showed similar shifts. It was reported that Pt species could spill over H₂ to the neighboring Ce–O bond [35,36], which caused the reduction peaks of CeO₂ to appear at lower temperatures. To further compare the low-temperature reducibilities, we calculated the total H₂ consumption of the samples, as summarized in Table 4. The H₂ consumption below 200 °C showed a sharp rise for PC-P, PC-TP, and PC-PT to 128, 135, and 182 µmol g⁻¹, respectively, while the values of H₂ uptake for the PC-U and PC-T samples were around 50 µmol g⁻¹. Note that the nominal value of H₂ consumed by loaded Pt species should be 28 µmol g⁻¹. Thus, the excess H₂ uptake of the samples was ascribed to the spillover effect, causing the reduction of Ce⁴⁺ ions that were adjacent to Pt species. Hence, the first peak should be not only assigned to the reaction of PtO₂ with H₂ at low temperatures but also the reduction of active oxygen species derived from ceria that interacted with Pt [37]. Therefore, the increased H₂ consumption of PC-PT compared to that of PC-T may indicate that the Pt-Ce interaction was enhanced due to the plasma treatment. The differences of the reduction temperature and H₂ consumptions of PC-PT and PC-TP were attributed to their different reducibilities caused by the various treatment sequences, and the combined treatment with a certain sequence could facilitate the reduction of surface oxygen on the Pt/CeO₂ catalyst.

To further investigate the redox properties of the samples, the O₂-TPD profiles are shown in Figure 7. There are three peaks in the traces of the samples. The peaks of PC-PT appeared at 104, 254, and 436 °C. The peak temperatures of the other samples were higher compared to that of PC-PT, and the lower peak position indicated that oxygen is more likely to migrate over the catalyst. In general, the oxygen adsorbed by the catalyst underwent the following process: O₂ (ad) → O₂⁻ (ad) → O⁻
The peaks were assigned as follows: the peak below 200 °C was related to \( \text{O}_2^- \) (ad), the peak in the 200–400 °C range was related to chemically adsorbed oxygen \( \text{O}^- \) (sur), and the peak above 400 °C was related to \( \text{O}^2^- \) (lat). The amounts of \( \text{O}_2^- \) (ad) and \( \text{O}^- \) (sur) are listed in Table 4. As shown, the intensity of the \( \text{O}_2^- \) (ad) peak showed significant variations among the samples. The total \( \text{O}_2^- \) (ad)/\( \text{O}^- \) (sur) can be used as an index to compare the oxygen utilization ability of the catalysts [39]. As calculated from Table 4, the \( \text{O}_2^- \) (ad)/\( \text{O}^- \) (sur) value of PC-PT was highest at 2.0 and followed by PC-TP at 1.7, while the \( \text{O}_2^- \) (ad) ratio of PC-T was 1.5, which indicated that the combined treatment could enhance the catalysts’ oxygen utilization ability to various extents. It was consistent with XPS results that PC-PT showed a higher \( \text{O} \text{ads} \) ratios than PC-TP. Moreover, oxygen vacancy was regarded as oxygen adsorbed and desorbed center, which acted a bridge to adsorb active gaseous oxygen [40]. Thus, the \( \text{O}_2 \) adsorption of each sample could be related to various oxygen vacancies, which might influence the catalytic performance.

![Figure 7. O2-TPD profiles of different Pt/CeO2 samples.](image)

To study the role of oxygen vacancies for the catalysts and investigate the crystallinities of the samples, UV-Raman was performed, and the results are shown in Figure 8. Three typical peaks appeared in the Raman spectra at 457, 588, and 1174 cm\(^{-1}\). Generally, the first peak corresponded to the \( \text{F}_{2g} \) mode, due to the symmetrical stretching vibrations of Ce–O in fluorite CeO\(_2\) [41]. The second peak was attributed to a defect-induced mode (D), which was related to oxygen vacancies caused by Ce\(^{3+}\) defects. The third peak was distinguished as a second-order longitudinal optical (2LO) mode [42]. To identify the samples’ relative oxygen vacancy concentrations, the ratios of the \( \text{F}_{2g} \) and defect-induced modes (\( \text{I}_D/\text{I}_{\text{F}_{2g}} \)) were determined, and the values were in the following order: PC-U (1.55) < PC-T (1.73) < PC-P (2.49) < PC-TP (2.52) < PC-PT (2.82). As shown in Table 4, the \( \text{I}_D/\text{I}_{\text{F}_{2g}} \) ratios of plasma-treated samples increased sharply, as compared to those of samples without plasma modification. For example, the \( \text{I}_D/\text{I}_{\text{F}_{2g}} \) ratio of PC-P was 2.49 but the \( \text{I}_D/\text{I}_{\text{F}_{2g}} \) of PC-T was only 1.73. The results were in accord with the Ce\(^{3+}\) ratio estimated from the XPS test. Since the \( \text{I}_D/\text{I}_{\text{F}_{2g}} \) ratio could also reflect the relative concentration of oxygen vacancies, it was therefore evident that plasma could induce the formation of more oxygen vacancies.

surface values were determined and are summarized in Table 4. The calculated values were as follows: PC-U (40.1 μmol O g\(^{-1}\)), PC-T (58.2 μmol O g\(^{-1}\)), PC-P (99.3 μmol O g\(^{-1}\)), PC-TP (102.9 μmol O g\(^{-1}\)), and PC-PT (125.1 μmol O g\(^{-1}\)), which agreed with the Raman data. Thus, thermal or plasma treatment could enhance the catalyst oxygen vacancies, and a greater number of oxygen vacancies were present in the plasma-modified samples, while the effect of sole thermal treatment was slight. PC-PT, which underwent thermal treatment after plasma treatment, exhibited the greatest number of oxygen vacancy sites. This indicates that the combined treatment of Pt/CeO\(_2\) was conducive to the formation of oxygen vacancies. However, different results between PC-PT and PC-TP implied that various treatment sequences could also affect the oxygen vacancies.

3. Discussion

From the results of XRD, XPS and H\(_2\)-TPR, it was concluded that plasma played a vital role in promoting the surface interaction. It was reported that promoted surface interaction could enhance catalyst’s thermal stability and increase the number of oxygen vacancies over catalyst surface [26,33]. The effects of plasma on surface interaction were also clarified. The energetic species in discharge stroke and etched the catalyst surfaces, scattered Pt particles from agglomerated Pt, and produced small particles. Laura et al. [16] proposed that the plasma might generate electron-enriched Pt particles, which could interact with the ceria support strongly. Highly dispersed Pt particles were conducive to interactions with active supports. The plasma probably promoted the Pt atom to enter into CeO\(_2\) surface layer and enhanced the interaction between Pt and CeO\(_2\). Through the plasma-assisted interaction, catalysts’ thermal stability enhanced, as the XRD and BET results proved.

Moreover, the plasma affected the generation of oxygen vacancies. Excited species with various energy levels were likely to break their molecular bond. When excited species with high energies approached the catalyst surface, they could transmit energy to the Ce–O asymmetrical bond through collision dissociation [43]. Subsequently, the Ce–O bonds were broken, and Ce- defects formed when the excited O* possibly escaped from the surface directly or reacted with H\(_2\) species. The inference was proven by a significant increase in the oxygen vacancies amount of PC-P, as compared with that of PC-U. In addition, the bombardment of excited species could promote the Pt-Ce interaction and resulted in electronic enrichment of the catalyst surface. Electron-enriched Pt would interact with the adjacent Ce–O bonds, causing the relaxation of Ce–O, which made it vulnerable to reaction with H\(_2\) and decreased the energy barrier for the formation of oxygen vacancies. Wang et al. [44] confirmed
that the interaction between the metal and support affected the oxygen vacancy formation energy and played a vital role in oxygen vacancy generation. Alayoglu et al. [45] also reported that the oxygen species of CeO$_2$ that had interacted with platinum were consumed by H$_2$ and formed new oxygen vacancies. Thus, when the subsequent H$_2$/N$_2$ thermal condition was added to plasma-excited catalyst, the H$_2$ species that were activated by the thermal condition would react with the Pt-interacted Ce–O bonds and generate more Ce-defects. As a result, PC-PT contained more oxygen vacancies than PC-P and PC-TP, which did not receive subsequent thermal treatment. The details are shown in Figure 9. It was clear that the plasma could enhance the generation of oxygen vacancies and surface interaction between precious metal and supports.

![Figure 9. Modification mechanism of PC-PT.](image)

According to Mars-van Krevelen reaction mechanism, toluene oxidation on Pt/CeO$_2$ is followed by the activation of adsorbed toluene and dissociative O$_2$. Combining TEM, OSC test and activity evaluation, it was found that PC-PT with small particle sizes could expose more Pt atoms and increase the amount of toluene molecules adsorbed by the catalyst, and a large number of oxygen vacancies over PC-PT could facilitate the dissociative O$_2$ adsorption and activation. Hence, PC-PT showed the best catalytic activity. Moreover, PC-PT and PC-TP underwent plasma and thermal treatment, but their different treatment sequences caused their variety in characterization. From the TEM results, PC-PT and PC-TP had similar Pt particle sizes, but the data from the OSC tests confirmed that they contained different numbers of oxygen vacancies, which explains why the PC-PT exhibited a better catalytic activity than PC-TP. Evidently, the treatment sequence of the combined treatment could deeply affect toluene catalytic oxidation of Pt/CeO$_2$ and the role of plasma in combined treatment sequences determined catalysts’ performances.

4. Materials and Methods

4.1. Catalysts Preparation

The CeO$_2$ nanorod supports were prepared as follows. First, 1.586 g of cerium acetate (5 mmol) was dissolved in deionized water, after which 55 ml NaOH solution (7 mol L$^{-1}$) was added. The mixed translucent solution was stirred for 0.5 h at room temperature, and then transferred to a 100 ml autoclave for hydrothermal treatment for 5 h at 130 °C. After the hydrothermal treatment was completed, the obtained precipitate was washed with deionized water and ethanol until the pH reached 7 and dried at 100 °C for 5 h. Next, Pt/CeO$_2$ was synthesized through an incipient-wetness impregnation method as follows. The previously synthesized CeO$_2$ was impregnated in a solution of Pt(NO$_3$)$_2$ at a concentration to yield a final loading content of 0.8 wt %. The impregnated Pt/CeO$_2$ catalysts were calcined at 300 °C for 3 h in dry air, and the obtained catalyst was denoted as PC-U. PC-U that was subsequently plasma-treated for 3 h was denoted as PC-P. The PC-P and PC-U samples that were thermally treated at 300 °C for 3 h in 20% H$_2$/N$_2$ (MESSER, Foshan, China) were respectively denoted as PC-TP and PC-T. Finally, PC-T was then treated by plasma to obtain a sample denoted as PC-TP.

All the chemicals were purchased from Aladdin, Shanghai, China.
4.2. Experimental Setup

A schematic of the overall experimental setup is shown in Figure 10. The plasma treatment occurred in a dielectric barrier discharge (DBD) reactor (CTP-2000K, Suman, Nanjin, China) due to its facile operation requirements (room temperature and atmospheric pressure). A constant AC (Alternating Current) power of 4.8 W (frequency of 1.77 kHz) was supplied to power the DBD reactor. A stainless-steel high-voltage electrode (2 mm diameter) was set in the center of the quartz tube (6 mm diameter) as the inner electrode, and copper foil was wrapped around the tube as the outer electrode. The discharge gap between high-voltage electrode and quartz was maintained at 2 mm, and the length of the discharge area was 50 mm. During the discharge, 0.5 g catalyst was introduced to the discharge zone, and a reducing gas (20% H$_2$/N$_2$ with 100 ml min$^{-1}$ flow rate) was used as the carrier gas in the plasma reactor to intensify the electron collisions on the catalyst. The exhaust gas was monitored by gas chromatography (GC-2014C, SHIMADZU, Kyoto, Japan) equipped with a flame ionization detector (FID). The toluene concentration and flow rate were controlled at 200 ppm and 100 ml min$^{-1}$, respectively, by mass flow controllers (MFCs).

4.3. Catalysts Characterization

The amount of loaded Pt was measured by inductively coupled plasma/optical emission spectroscopy (ICP-OES, Perkin-Elmer plasma 8000, Norwalk, CT, USA). XRD analysis of the catalysts was performed using a Bruker D8-ADVANCE X-ray diffractometer (Bruker, Karlsruhe, Germany) equipped with Cu Kα radiation (40 kV and 40 mA, scanning step = 0.02). Nitrogen adsorption and desorption isotherms were tested on a Micromeritics ASAP 2020 system (Micromeritics, Atlanta, GA, USA) to calculate the specific surface area ($S_{BET}$).

XPS analyses of the catalysts were conducted using a Thermo ESCALAB250 (Waltham, MA, USA). The binding energies were determined relative to that of adventitious carbon (C1s), whose binding energy is 284.6 eV. UV-Raman spectra were measured using a LabRAM HR Evolution Laser Raman Spectrometer (HY, France) with a 325 nm laser excitation source and a spectrometer with 2400 grooves mm$^{-1}$.

---

Figure 10. Schematic diagram of the experimental setup. The discharge condition was set for 3h with 4.8 W of input power, 1.77 kHz AC frequency, catalyst amount was fixed at 0.5 g.
HRTEM images were obtained using a Tecnai G2 F20 S-TWIN (Hillsboro, OR, USA). The average diameters of Pt particles ($d_{1\text{Pt}}$) and their dispersion ($D_{1\text{Pt}}$) were calculated based on the HRTEM images of the catalyst using the following formulas:

$$d_{1\text{Pt}} \approx \frac{\sum n_i d_i}{\sum n_i}$$  \hspace{1cm} (1)

$$D_{1\text{Pt}} = \frac{600 M_{\text{Pt}}}{\rho_{\text{Pt}} d_{1\text{Pt}} a_{\text{Pt}} N_A}$$ \hspace{1cm} (2)

where $n_i$ represents the number of particles of diameter $d_i$ (nm), $M_{\text{Pt}}$ represents the molar mass of Pt (195.08 g mol$^{-1}$), $\rho_{\text{Pt}}$ denotes the density of Pt (21.45 g cm$^{-3}$), $a_{\text{Pt}}$ is the cross-sectional area of a Pt atom ($8.06 \times 10^{-20}$ m$^2$ atom$^{-1}$), and $N_A$ is the Avogadro constant ($6.019 \times 10^{23}$ atom mol$^{-1}$).

CO-chemisorption, H$_2$-TPR, O$_2$-TPD, and OSC tests were performed using a chemisorption analyzer (Micromeritics Chemisorb 2920II, Micromeritics, Norcross, GA, USA). For CO-chemisorption, a 50 mg sample was deposited in a U-shaped quartz tube and exposed to Ar flow (30 ml min$^{-1}$) at 300 °C for 1 h. After the sample was cooled to ambient temperature, a 10% CO/Ar (30 ml min$^{-1}$) stream was periodically injected into the tube until the catalyst achieved adsorption saturation. For H$_2$-TPR, a 50 mg sample was pretreated at 300 °C with 5% O$_2$/He (30 ml min$^{-1}$) mixed gas for 1 h, after which it was cooled to 50 °C by Ar (30 ml min$^{-1}$). Subsequently, the gas flow into the tube was changed to 10% H$_2$/Ar (30 ml min$^{-1}$) and the samples were heated to 700 °C. For O$_2$-TPD, a 50 mg of sample was pretreated in He flow (30 ml min$^{-1}$) at 300 °C for 1 h. The gas flow was changed to 10% O$_2$/He (30 ml min$^{-1}$) at 300 °C for 1 h. Subsequently, the sample was cooled to 60 °C and allowed to adsorb 5% O$_2$/He (30 ml min$^{-1}$) mixed gas at 60 °C for 1 h, and then heated up to 700 °C with He purging (30 ml min$^{-1}$). For OSC, about a 50 mg sample was first pretreated by He flow (30 ml min$^{-1}$) for 1 h at 300 °C, after which it was cooled to ambient temperature, followed by the periodic injection of 5% O$_2$/He (30 ml min$^{-1}$) until saturation was achieved.

The diameter ($d_{2\text{Pt}}$) of a Pt particle and corresponding dispersion ($D_{2\text{Pt}}$) based on the CO-chemisorption were calculated as follows:

$$d_{2\text{Pt}} \approx \frac{60 X_{\text{Pt}}}{\rho_{\text{Pt}} S_{\text{Pt}}}$$ \hspace{1cm} (3)

$$D_{2\text{Pt}} = \frac{10 S_{\text{Pt}} M_{\text{Pt}}}{X_{\text{Pt}} a_{\text{Pt}} N_A}$$ \hspace{1cm} (4)

where $X_{\text{Pt}}$ denotes the Pt loading and $S_{\text{Pt}}$ represents for Pt relative surface area obtained by the CO chemisorption (m$^2$ g$^{-1}$). The stoichiometric ratio between the Pt atoms and CO was defined to be 1:1.

The number of surface oxygen vacancies (OSC$_{\text{surface}}$) was obtained from the following equations:

$$\text{OSC}_{\text{Pt}} = 2 \frac{D_{1\text{Pt}} X_{\text{Pt}}}{M_{\text{Pt}}}$$ \hspace{1cm} (5)

$$\text{OSC}_{\text{surface}} = \text{OSC}_{\text{catalyst}} - \text{OSC}_{\text{Pt}}$$ \hspace{1cm} (6)

where OSC$_{\text{catalyst}}$ represents the consumption of oxygen by catalyst, and it was calculated by the OSC test; OSC$_{\text{Pt}}$ represents the oxygen consumption for Pt alone, and $M_{\text{Pt}}$ is the molar mass of Pt (195.08 g mol$^{-1}$). The stoichiometric ratio of Pt and oxygen atoms was defined to be 1:2.

4.4. Catalytic Evaluation

Before catalytic evaluation, the samples (100 mg, 40–60 mesh) diluted with 400 mg of silicon (40–60 mesh) were packed in the bed of the quartz reaction tube (8 nm internal diameter and 50 cm length). Subsequently, 200 ppm toluene carried by 100 ml min$^{-1}$ of air (20% O$_2$/N$_2$) was sent into the tube to evaluate the catalytic activity. The activation energies (Ea) were calculated at 125–145 °C, at which the toluene conversion is less than 10%. T$_{50}$ and T$_{100}$ were regarded as indices of catalytic
evaluation, which respectively denote the temperature of toluene conversions of 50% and 100%. The conversion ($\eta$) of toluene by oxidation was calculated by the formula:

$$\eta = \frac{C_{in} - C_{out}}{C_{in}} \times 100,$$

where $C_{in}$ denotes the inlet toluene concentration (ppm) and $C_{out}$ denotes the outlet toluene concentration (ppm).

The turnover frequencies (TOFs) were calculated using the following formulas:

$$\text{TOF}_{Pt} \left( S^{-1} \right) = \eta F_{toluene} \frac{M_{Pt}}{m_{\text{cat}}X_{Pt}D_{Pt}},$$

$$\text{TOF}_{OV} \left( S^{-1} \right) = \eta F_{toluene} \frac{1}{m_{\text{cat}}OSC_{surface}},$$

where $\text{TOF}_{Pt}$ and $\text{TOF}_{OV}$ are the turnover frequencies based on the Pt particles and oxygen, respectively, $\eta$ is the toluene conversion at 150 °C, $F_{toluene}$ is the toluene velocity (mol s$^{-1}$), and $m_{\text{cat}}$ is the mass of the catalyst (g).

Activation energies ($E_a$) were based on the “mol-Pt-surface”, and the formula was as follows:

$$\ln r^* = -\frac{E_a}{RT} + \ln A$$

$$r^* = \frac{rM_{Pt}}{D_{Pt}X_{Pt}}$$

where $r$ represents for reaction rate (mol s$^{-1}$); $E_a$ represents for activation energy (kJ mol$^{-1}$); $R$ is the universal gas constant (kJ mol$^{-1}$ K$^{-1}$); $T$ is the temperature of reaction (K).

5. Conclusions

Plasma-assisted treatments influenced the size of Pt particles, the number of surface oxygen defects on CeO$_2$, and the interface reaction between Pt and CeO$_2$. Plasma modification improved catalysts’ thermal stability and inhibited the sintering of the catalysts in high temperature, resulting in greater exposure of active sites. Compared to catalysts without plasma treatment, the Pt particle sizes of catalysts treated by plasma decreased and high dispersion was obtained. The greater number of oxygen vacancies produced was ascribed to Pt-Ce interactions promoted by the combination of plasma and thermal treatments. Catalysts modified by different treatment sequences contained different concentrations of oxygen vacancies, which resulted in various activation energies for toluene oxidation. Moreover, the PC-PT sample exhibited the best catalytic activity, with $T_{50} = 167$ °C and $T_{100} = 205$ °C. Therefore, plasma modification followed by thermal treatment has great potential for future catalyst preparation.
