Abstract: A hybrid composite photodetector based on cesium lead bromide perovskite (CsPbBr$_3$) nanosheets and carbon nanodots (CDs) was fabricated on a quartz substrate by a one-step method of spin-coating and hot-plate annealing. The responsivity of the CsPbBr$_3$/CD hybrid composite photodetector was 608 mAW$^{-1}$ (under a 520-nm laser diode source applied at 0.2 mWcm$^{-2}$), almost three times higher than that of a CsPbBr$_3$-based photodetector (221 mAW$^{-1}$). The enhanced performance of the CsPbBr$_3$/CD photodetector is attributable to the high band alignment of the CDs and CsPbBr$_3$, which significantly improves the charge extraction at the CsPbBr$_3$/CD interface. Moreover, the hybrid CsPbBr$_3$/CD photodetector exhibited a fast response time with a rise and decay time of 1.55 and 1.77 ms, which was faster than that of a pure CsPbBr$_3$ based photodetector, indicating that the CDs accelerate the extraction of electrons and holes trapped in the CsPbBr$_3$ film.

Keywords: all-inorganic perovskite; CsPbBr$_3$; carbon nanodots; charge transfer; carrier separation; photodetectors

1. Introduction

Organic–inorganic halide perovskites have shown high performance in photodetectors [1–5], owing to their outstanding electrical and optical properties, including tunable bandgap [6], strong optical absorption [7], long carrier diffusion length [8], large carrier mobilities [9], and low deep state defects [10]. Moreover, they can be fabricated by low-cost, low-temperature solution-processing techniques such as drop-casting [11], spray-coating [12], spin-coating [13], and doctor-blading [14]. Accordingly, they are future candidate materials for low-cost, facile, flexible, and large-scale printable photodetectors [2,15]. Among the organolead halide perovskites, all-inorganic lead halide perovskites CsPbX$_3$ (X = I, Br, Cl) are recognized for their high stability in humid environments (unlike organic–inorganic halide perovskites), high absorption coefficient ($2 \times 10^5$ cm$^{-1}$) [16], and large carrier mobility (1000 cm$^2$ V$^{-1}$S$^{-1}$) [17]. With these outstanding electrical and optical properties, photodetectors based on all-inorganic lead halide perovskites should strongly outperform devices based on organic–inorganic halide perovskites or 2D MoS$_2$, reaching the performance of silicon-based devices [18,19]. However, the actual performance of solution-processed photodetectors based on all-inorganic perovskite film has been unsatisfactory, exceeded not only by devices based on 2D MoS$_2$ or silicon, but also by photodetectors based on...
organic–inorganic hybrid perovskites [20–22]. Later, this poor performance was linked to the low conductivity of solution-assembled film resulting from poor continuity of the film, which inevitably creates interfacial traps that lower the carrier extraction and transport efficiency [19]. The performance can be enhanced by fabricating bilayer heterostructure photodetectors, in which the perovskite layer (which absorbs the light) is combined with another functional material such as graphene or a 2D material (which transports the photocarriers). A hybrid phototransistor based on graphene–CsPbBr$_3$-I$_x$ perovskite nanocrystals achieved a high photo-responsivity of 108 A W$^{-1}$ and a detectivity of 10$^{16}$ Jones under 405-nm illumination at 0.07 mW$^{-2}$ [23]. Song et al. [24] fabricated a hybrid photodetector based on 2D MoS$_2$ and CsPbBr$_3$ nanosheets, which exhibited high photoresponsivity (4.4 AW$^{-1}$), an external quantum efficiency of 302%, and a detectivity of 2.5 × 10$^{10}$ Jones. Although these devices achieved excellent performance, the transfer method of the graphene and 2D Mos$_2$ (mechanical exfoliation) is complicated and expensive, and hence inappropriate for flexible and large-area fabrication.

Carbon nanodots (CDs) (novel nano-sized carbon structures) have also demonstrated excellent performance in applications such as photocatalysis [25], bioimaging [26], and supercapacitors [27]. CDs are favored for their excellent photoluminescence [28], low toxicity [29], biocompatibility [30], simple synthesis [31], and high stability [32]. In optical and optoelectronic applications, CDs have been mainly exploited in light-emitting diodes [33–35]. They also boost the performance of optical devices by providing an electron transportation layer. Xie et al. [36] reported a core shell heterojunction photovoltaic device composed of a silicon nanowire array and carbon quantum dots, which reached a power conversion efficiency of 9.10% under AM1.5G irradiation. Guo et al. [37], fabricated a photodetector based on zinc oxide quantum dots and CDs, which achieved a detectivity and noise equivalent power of 3.1 × 10$^{17}$ cmHz$^{1/2}$/W and 7.8 × 10$^{−20}$ W, respectively. Moreover, in photosensing applications, it has been demonstrated that the photoresponsivity of p–n junction based photodetectors can be increased by the use of graphene nanosheets composites [38,39]. Dai et al. [40], demonstrated transparent and flexible (TFT) based on solution processed–graphene nanosheets and amorphous indium–gallium–zinc-oxide (a-IGZO) composites, with an achieved mobility of 23.8 (cm$^2$/V·s) and CsPbBr$_3$-I$_x$ perovskite nanosheets, which exhibited high photoresponsivity (4.4 AW$^{-1}$), an external quantum efficiency of 302%, and a detectivity of 2.5 × 10$^{10}$ Jones. Although these devices achieved excellent performance, the transfer method of the graphene and 2D Mos$_2$ (mechanical exfoliation) is complicated and expensive, and hence inappropriate for flexible and large-area fabrication.

In this work, we fabricate a solution-processed hybrid photodetector based on all-inorganic cesium lead bromine (CsPbBr$_3$) perovskite nanosheets and CDs. The CDs are combined with perovskite to enhance the transport and separation of the photogenerated carriers in the perovskite. Here we exploit the excellent alignment of CDs with the perovskites, which restricts the recombination rate of the photogenerated carriers and enhances the photocurrent over the CsPbBr$_3$ device without CDs. We demonstrate the higher performance of the hybrid CsPbBr$_3$/CD composite photodetector (with an on/off ratio of 102 and a responsivity of 608 mAW$^{-1}$) than the CD-free perovskite-based photodetector (with a responsivity of 221 mAW$^{-1}$).
2. Materials and Methods

Starting materials: All materials were purchased from Aladdin (Shanghai, China) and Sigma Aldrich (Seoul, Korea) and used without further purification.

Preparation of perovskite nanosheets: The CsPbBr$_3$ nanosheets were synthesized by the method in Song [24]. First, CsBr and PbBr$_2$ (molar ratio 1:0.5) were dissolved by ultrasonication in 15 mL of dimethyl sulfoxide for 1 h, yielding a mixed solution. Second, 0.2 mL of the as-prepared solution was dropped into 1 mL octadecylamine and acetic acid solution (50 mg/mL) and magnetically stirred for 2 min. Then, 15 mL of toluene was injected into this solution. After a few minutes, the solution was centrifuged, and the collected precipitate was redispersed in toluene and centrifuged once more. Finally, the precipitate was dispersed in 4 mL of toluene to form 2 mg/mL perovskite solution.

Preparation of carbon nanodots: The carbon nanodots (CDs) were prepared by the method in Barman [42]. First, an aqueous solution was prepared by mixing 0.1 g of branched polyethylenimine with 10 mL of hot water. After adding 0.1 g citric acid and stirring the solution for 1 h, we transferred the prepared solution to an autoclave and heated it at 230 °C for 5 h. The solution was cooled to room temperature, centrifuged, and purified by dialysis. Finally, the CDs were collected from the solution after drying for 24 h at 75 °C in a high vacuum, and frozen for further use.

Preparation of CsPbBr$_3$/CD composite solution: The dried CDs were dispersed in 2 mL of ethanol to form a 4 mg/mL CD solution. The CsPbBr$_3$/CD composite solution was then prepared by mixing the perovskite nanosheets and CD solutions at a volume ratio of 1:0.25. The composite solution was stirred for 12 h and used without further modification.

Characterization of materials: The crystal structures and morphologies of the products were analyzed by transmission electron microscopy (TEM, JEM-F200, Tokyo, Japan), field-emission scanning electron microscopy (SEM, JEOL-7800F, Tokyo, Japan), and atomic force microscopy (AFM, NX-10-Park Systems). The X-ray diffraction (XRD, Ultima IV, Rigaku, Tokyo, Japan) patterns were obtained by a diffractometer (Ultima IV; Rigaku). The optical spectra were characterized by a photoluminescence (PL) spectrophotometer (OPTIZEN 3220UV, Agilent Technologies Inc., USA) and an ultraviolet–visible light (UV–vis) spectrophotometer (JASCO V-650, JASCO Deutschland GmbH, Pfungstadt, Germany).

Device fabrication process: A quartz substrate (SK-1300 series, 2.5 × 2.5 cm$^2$, OHAIR Quartz Co. Ltd., Seoul, Korea) was ultrasonically cleaned with acetone and isopropanol, then rinsed with deionized water and dried under an N$_2$ flow. Subsequently, the substrate was treated by O$_2$ plasma for 15 min, and the Cr/Au (4/80 nm) electrodes were fabricated by standard lithography, thermal evaporation, and the wet etching process. The channel length and width of the electrodes were 20 and 1000 µm, respectively. The composite solution was then spin coated on the treated substrate at 2000 rpm for 10 s and annealed at 100 °C for 15 min.

Device performance measurements: The photoelectric current–voltage (I–V) characteristics were obtained by a measurement system equipped with a Keithley 4200 SCS parameter analyzer, and a 520-nm laser diode as the light source (MDL-III-520L, Changchun New Industries Optoelectronics Technology Co. Ltd., Changchun, China). The current–time (I–t) characteristics were obtained under the same laser diode source and a Keithley 4200 SCS with an optical chopper (SRS, SR540) at 1 Hz. The response time was measured under the same laser diode source, optical chopper (f = 100 Hz), and an oscilloscope (model TDS3012, Tektronix).

3. Results and Discussion

3.1. Device Structure

Figure 1 illustrates the structure of the CsPbBr$_3$/CD hybrid composite photodetector fabricated on the quartz substrate. Initially, Cr/Au (4 nm/80 nm) were thermally deposited on the quartz substrate by standard lithography, thermal evaporation, and wet etching, yielding electrodes with a total effective area of 2 × 10$^{-4}$ cm$^2$ (Figure S1). The left image in Figure 1 shows the emission colors of the CsPbBr$_3$ and CD solutions under white light. The CsPbBr$_3$ solution emitted typically yellow light while the
CD solution showed a watery emission [22,42,43]. The right image in Figure 1 is a schematic of the composite materials containing mixed perovskite nanosheets and CDs. The small square shows the unit cells of CsPbBr₃ and the CDs. The unit cell of perovskite nanosheets is typically a cubic structure formed by Pb and Br bonded to both Cs atoms [44]. In contrast, the carbon nanodots form a spherical graphitic-like structure [45]. The CsPbBr₃/CD composite film on glass was almost 200 nm thick (as verified by a step profiler) and was both compact and uniform (Figure S2). It is also worth mentioning that the film thickness of the CsPbBr₃/CD composite film (200 nm) was actually thinner than that of the pure CsPbBr₃ film (228 nm), which indicated that the thickness of composite film was slightly reduced when the carbon nanodots were incorporated [46]. This could have resulted from viscosity changes of the composite solution after the addition of the carbon nanodots. However, as discussed later in this section, the morphology of the CsPbBr₃ and CsPbBr₃/CD composite film was analyzed to point out the role of the CDs.

![Figure 1. Schematic of the device structure and composite materials.](image)

### 3.2. Characterization of CDs, CsPbBr₃, and CsPbBr₃/CD Composite Solutions

The crystal structures and qualities of the CDs, CsPbBr₃, and CsPbBr₃/CD were determined from the low-magnification and high-resolution (HR) TEM images and from Fourier transform images (see Figure 2). The CDs were narrowly distributed in size, with an average diameter of ~4.5 nm (Figure 2a). The lattice fringes (0.21 nm) of the CD structure are clearly seen in Figure 2b (see also Figure S3a), and the fast Fourier transform image of the selected area (enclosed by the dashed red circle in Figure 2b) revealed the high crystallinity of the CDs [43,45]. TEM and HRTEM images of the CsPbBr₃ nanosheets are shown in Figure 2d,e, respectively (see also Figure S3b). These images clarified the cubic structure of the perovskite nanosheets, with a lattice fringe of approximately 0.58 nm [22]. Moreover, the Fourier transform image in Figure 2f confirmed the crystalline structure of perovskite. Meanwhile, in the TEM image of the sample combining the CDs with the CsPbBr₃ nanosheet solution, evidence of both materials was expected. The presence of both materials was indeed confirmed in TEM images of the composite sample (Figure 2g,h,k). Carbon nanodots (dashed red circles) and perovskite nanosheets (green-lined square) are clearly shown in Figure 2k. Moreover, to clarify that these nanodots were CDs alone, we magnified their structure, as seen in Figure S3c,d. These images clearly reveal the hexagonal honeycomb structure of graphite [45].
Figure 2. TEM, HRTEM, and Fourier transform images of typical carbon nanodots (a), (b), (c) (top row) and CsPbBr\(_3\) (d), (e), and (f) (middle row). Bottom row shows an HRTEM image of the CsPbBr\(_3\)/CD composite (g), a magnified HRTEM image of the yellow box in (g) (panel (h)), and a magnified image of the blue box in (g) (panel (k)). In (k), the dashed red circles and green-lined square outline the carbon dots and a CsPbBr\(_3\) nanosheet, respectively.

The CsPbBr\(_3\) and CsPbBr\(_3\)/CD composite films were further characterized by their powder XRD patterns. The XRD spectra are displayed in Figure 3. The peaks in the spectra of the CsPbBr\(_3\) film, labeled 100, 110, 200, 210, 211, and 220, corresponded to the cubic crystalline structure of CsPbBr\(_3\) nanosheets as reported elsewhere [22]. However, the peaks in the XRD spectra of the CsPbBr\(_3\)/CD corresponded only to the cubic structure of CsPbBr\(_3\); the characteristic CD peaks were absent. According to the literature, the XRD patterns of CDs exhibit one peak between \(2\theta = 20^\circ\) and \(2\theta = 30^\circ\) (depending on the size, structure, and synthesis process of the CDs) [47]. The discrepancy might be attributable to coverage of the 4.5 nm-diameter CDs by the considerably larger perovskite nanosheets, which might have dominated the XRD detection. Supporting this idea, the XRD pattern of perovskite and carbon nanotube composite film in a previous study showed only the peaks of the perovskite structure [48].
3.3. Optical characterization of the CDs, CsPbBr₃, and CsPbBr₃/CD Composite Solutions

The optical properties of the CDs, CsPbBr₃, and CsPbBr₃/CD composite solutions were characterized by their UV–vis spectra. As shown in Figure 4a, the solution of pure CDs absorbed in the deep-to-near UV region with a peak near 405 nm, corresponding to a bandgap of 3.61 eV [42,43]. In contrast, the CsPbBr₃ solution absorbed wavelengths from the UV to the visible region with an absorption peak at 520 nm, corresponding to a bandgap of 2.4 eV [22,24]. The absorption spectrum of the CsPbBr₃/CD composite solution displayed the same characteristics as that of pure CsPbBr₃ solution, corresponding to the same bandgap. This result indicated that photon absorption by the composite film was dominated by perovskite. Moreover, the absorption intensity was lower in the CsPbBr₃/CD composite solution than in pure CsPbBr₃ solution. This was confirmed by naked-eye observation under white and UV (365-nm) light: the CsPbBr₃/CD composite solution was lighter in color than the pure CsPbBr₃ solution (see insets of panels (a) and (b) of Figure 4, respectively).

![Figure 3. X-ray powder diffraction (XRD) patterns of CsPbBr₃ and CsPbBr₃/CD film.](image)

![Figure 4. Absorption spectra of CsPbBr₃ and CsPbBr₃/CD film (a), photoluminescence spectra of the carbon nanodots, CsPbBr₃, and CsPbBr₃/CD composite (b), energy-band structures of perovskite (yellow) and CDs (cyan) with green arrow representing electron transfer from conduction band of the perovskite into the conduction band of the CDs (c), and hypothesized recombination mechanisms in pure CsPbBr₃ and CsPbBr₃/CD composite (d). Insets in panels (a) and (b) show the colors of the solutions under white and UV light, respectively.](image)
The PL spectrometer is a powerful optical analyzer of the charge transfer and recombination processes in composite materials [49]. The PL spectra of the pure CDs, pure CsPbBr$_3$, and composite CsPbBr$_3$/CD solutions are presented in Figure 4b. The PL intensities of the pure CDs and CsPbBr$_3$ solutions peaked near the bandgap peaks. The higher intensity of the CsPbBr$_3$ peak than the CD peak indicated a higher recombination rate in perovskite than in pure CDs. However, the PL spectrum of the CsPbBr$_3$/CD composite solution peaked at a similar wavelength to the CsPbBr$_3$ solution, revealing that perovskite dominated the emission process in the composite solution. Nevertheless, the PL intensity was almost one order of magnitude lower in the composite solution than in pure CsPbBr$_3$, indicating a considerable amount of charge transfer at the CsPbBr$_3$/CD interface. In other words, the carbon nanotubes reduced the recombination rate of photogenerated carriers in the CsPbBr$_3$/CD, improving the light-absorance performance over that of pure perovskite in photosensing applications (as demonstrated later in this work). To understand the charge transfer across the CsPbBr$_3$/CD interface, we present the energy-band structures of the perovskite and CD materials in Figure 4c. This diagram shows the valence band maximum (VBM) and conduction band minimum (CBM) with respect to the vacuum level. The VBMs and CBMs of perovskite and CDs were obtained from Song et al. [24] and Barman et al. [42], respectively. The hybrid composite system showed a type-II band alignment with CBM and VBM offsets of 0.22 and 1.43 eV, respectively, from those of CsPbBr$_3$ perovskite and pure CDs. This type of band alignment suggested that the photogenerated electrons in perovskite moved into the CDs, while the photogenerated holes in perovskite were localized within the perovskite (owing to the raised CDM of the CDs). This analysis consolidated the PL spectra shown in Figure 4b, which hinted that the recombination rate was lower in the hybrid composite than in pure perovskite solution. To understand how the hybrid composite limited the recombination rate, we hypothesized the recombination mechanism in pure CsPbBr$_3$ and the CsPbBr$_3$/CD hybrid composite (see Figure 4d). When pure CsPbBr$_3$ absorbed photons with sufficient energy (similar to or greater than its own bandgap), electron–hole pairs were photogenerated in the perovskite, and the electrons moved from the valence to the conduction band, leaving empty spaces for the holes (absorption phenomenon). Within one picosecond, the conduction-band electrons relaxed and finally recombined with the holes in the valence band (the band-to-band recombination process) [46]. However, in the CsPbBr$_3$/CD hybrid composite, the recombination process was reduced because the electrons moved to the CDs while the holes localized within the perovskite, thus reducing the recombination probability.

3.4. Performances of Photodetectors Based on CsPbBr$_3$ and CsPbBr$_3$/CD Composite Film

The performance of a photodetector based on the CsPbBr$_3$/CD hybrid composite film was compared with that of a photodetector based on pure CsPbBr$_3$. The photoelectrical measurements were performed under a 520-nm laser diode with a light intensity of 0.2 mWcm$^{-2}$. The $I$–$V$ characteristics of the pure CsPbBr$_3$ and CsPbBr$_3$/CD hybrid composite photodetectors are shown in Figure 5a,b, respectively. It can be observed that the $I$–$V$ curves for the pure CsPbBr$_3$ and CsPbBr$_3$/CD hybrid composite photodetectors is symmetrical since the photocurrent value of each device (at −10 V and 10 V) were almost the same [24]. The dark currents of the photodetectors based on pure CsPbBr$_3$ and the CsPbBr$_3$/CD composite film were 0.09 and 0.12 nA under a 10-V bias voltage, respectively. This result was expected, as the CDs in the perovskite increased the conductivity of the hybrid photodetector. Similarly, under irradiation with 520-nm laser light at 0.2 mWcm$^{-2}$, the photocurrent of the CsPbBr$_3$/CD hybrid composite photodetector was 24.46 nA (versus 9 nA in the CsPbBr$_3$-based photodetector). To further confirm the photocurrent enhancement in the hybrid composite device, we obtained the $I$–$t$ curves by irradiating both devices with positive signals generated from the same 520-nm light source and a 1-Hz optical chopper [50]. The $I$–$t$ curves of both devices are presented in Figure 5c. Under the illumination conditions (0.2 mWcm$^{-2}$), the photocurrents of the pure CsPbBr$_3$–based and hybrid composite-based devices sharply increased when the bias voltage (10 V) was applied, reflecting the increase in carrier drift velocity. When the laser was turned off, the photocurrents sharply fell to their initial values. The devices promptly generated a photocurrent with a reproducible response in the
on–off cycles. In addition, the photocurrent was higher in the hybrid device than in the pure device, and both currents were similar to those measured in the $I$–$V$ curves under the same applied voltage. The response, rise, and decay times of the hybrid composite devices are illustrated in Figure 5d,e,f, respectively. The rise and decay times are the times required for the photocurrent to reach 90% of its peak value and decay to 10% of its peak value, respectively [51]. The hybrid photodetector exhibited a rise and decay time of 1.55 and 1.77 ms, respectively. The hybrid device not only showed a faster response time compared with that of the pure CsPbBr3 nanosheets (65.2 and 18.5 ms) reported by Song et al. [24], but also better than those of devices based on all-inorganic micro-particles [52] and nanorods [53]. This result confirmed two roles for the CDs in the hybrid composite device: enhancing the conductivity of the composite film, and accelerating the electron extraction. To realize the effect of the CDs on the device performance, we determined the on/off ratio (photocurrent to dark/current ratio) and the responsivity $R$ (electrical output per optical input) of the pure CsPbBr3 and CsPbBr3/CD hybrid composite photodetectors by Equations (1) and (2), respectively [54]:

$$I_{\text{ON/OFF}} = \frac{I_{\text{Light}}}{I_{\text{dark}}},$$

$$R = \frac{I_{\text{Light}} - I_{\text{dark}}}{P_{\text{Optical}} \times A}.$$  

In these expressions, $I_{\text{light}}$ and $I_{\text{dark}}$ are the dark current and photocurrent of the device, respectively, $P_{\text{Optical}}$ is the light power intensity, and $A$ is the effective illuminated area of the device. The on/off ratio of the CsPbBr3/CD composite photodetector was almost double that of the CsPbBr3 photodetector (217 vs. 102). Meanwhile, the $R$ of the CsPbBr3/CD composite device was 0.61 AW$^{-1}$, almost three times that of the Cd-free CsPbBr3 photodetector (0.22 AW$^{-1}$). Table 1 compares the responsivities of the CsPbBr3/CD hybrid composite photodetector and other reported devices. The proposed hybrid photodetector outperformed the previous devices based on CsPbBr3 nanosheets, quantum dots, and micro-particles. To further understand the role of the carbon nanodots in the performance enhancement of the all-inorganic perovskites, we analyzed the morphology of the CsPbBr3 and CsPbBr3/CD composite films using the AFM and SEM, as shown in Figures S4–S7. The top-surface SEM and AFM images of CsPbBr3 film revealed that the film had a high surface roughness with many defects, which resulted in poor performance (low conductivity) [19]. Moreover, when the CDs were blinded with the perovskite, the surface roughness of CsPbBr3/CD composite film was reduced and became more continues with fewer defects (Figure S8). As a result, the performance of the photodetector based on CsPbBr3/CD composite film was higher than that of the pure perovskite based photodetector.

3.5. Working Principle of the CsPbBr3/CD Composite Photodetector

The working mechanism of the composite photodetector can be explained by the energy-band structures of CsPbBr3 and the CDs, as seen in Figure 4c, which revealed a type-II band alignment at the interface. Under a light source with energy equal to or greater than the bandgap energy of the composite (i.e., ≥2.4 eV) [24], the CsPbBr3 absorbed photons, and the electrons in its valance band moved up to the conduction band, leaving their empty spaces as holes. The electrons in the conduction band of perovskite then moved downward into the conduction band of the CDs, because the CDs have higher electron affinity (a lower conduction band) than perovskite. Meanwhile, the holes remained in the valance band of perovskite because perovskite has a lower ionization potential (a higher valance band) than the CDs [24,37,46]. This type-II band alignment efficiently enhanced the charge separation at the CsPbBr3/CD interface, enhancing both the photocurrent and responsivity of the photodetector.
3.5. Working Principle of the CsPbBr₃/CD Composite Photodetector

The working mechanism of the composite photodetector can be explained by the energy-band structures of CsPbBr₃ and the CDs, as seen in Figure 4c, which revealed a type-II band alignment at the interface. Under a light source with energy equal to or greater than the bandgap energy of the composite (i.e., $\geq 2.4$ eV) [24], the CsPbBr₃ absorbed photons, and the electrons in its valance band moved up to the conduction band, leaving their empty spaces as holes. The electrons in the conduction band of perovskite then moved downward into the conduction band of the CDs, because the CDs have higher electron affinity (a lower conduction band) than perovskite. Meanwhile, the holes remained in the valance band of perovskite because perovskite has a lower ionization potential (a higher valance band) than the CDs [24,37,46]. This type-II band alignment efficiently enhanced the charge separation at the CsPbBr₃/CD interface, enhancing both the photocurrent and responsivity of the photodetector.

4. Conclusions

We fabricated a solution-processed hybrid photodetector based on perovskite (CsPbBr₃) nanosheets and carbon nanodot (CD) composite film. The composite film was prepared by mixing solutions of perovskite nanosheets (2 mg/mL) and CDs (4 mg/mL) at a volume ratio of 1:0.25. As revealed in the photoluminescence spectra, the CDs limited the recombination rate in the hybrid CsPbBr₃/CD composite photodetector.
composite film by significantly enhancing the charge extraction at the CsPbBr$_3$/CD interface. Moreover, the photoelectrical measurements confirmed a photocurrent of 24.46 nA in the CsPbBr$_3$/CD composite (versus 9 nA in the CsPbBr$_3$-based device), whereas the dark current was increased only to 0.11 nA (from 0.09 nA in the CsPbBr$_3$-based device). Consequently, the responsivity of the CsPbBr$_3$/CD hybrid composite photodetector was almost three times that of the CD-free CsPbBr$_3$ photodetector (608 mAW$^{-1}$ vs. 221 mAW$^{-1}$).
