The Effects of Royal Jelly Acid, 10-Hydroxy-Trans-2-Decenoic Acid, on Neuroinflammation and Oxidative Stress in Astrocytes Stimulated with Lipopolysaccharide and Hydrogen Peroxide

Amira Mohammed Ali 1,2,* and Hiroshi Kunugi 3,4

Abstract: The increased prevalence of neurodegenerative diseases, especially during the COVID-19 outbreak, necessitates the search for natural immune- and cognitive-enhancing agents. 10-Hydroxy-trans-2-decenoic acid (10-H2DA), the main fatty acid of royal jelly, has several pharmacological activities. Given the fundamental role of astrocytes in regulating immune responses of the central nervous system, we used cortical astrocytes to examine the effect of 10-H2DA on the expression of genes associated with neuroinflammation and the production of neurotrophins, as well as cellular resistance to H2O2-induced cytotoxicity. Astrocytes, pretreated with a range of concentrations of 10-H2DA for 24 h, were exposed to lipopolysaccharide (LPS) for 3 h, after which the expression of proinflammatory cytokines (IL-1β, IL-6, and tumor necrosis factor-α (TNF-α)) and neurotrophic factors (BDNF, GDNF, and IGF-1) was evaluated. In the absence of LPS, 10-H2DA had no significant effect on the mRNA expression of neurotrophins or cytokines except for IL-1β, which significantly increased with low doses of 10-H2DA (3 µM). 10-H2DA (10 µM) pretreatment of LPS-stimulated cells did not significantly inhibit the expression of cytokine encoding genes; however, it significantly lowered the mRNA expression of GDNF and tended to decrease BDNF and IGF-1 expression compared with LPS alone. Additionally, 10-H2DA did not protect astrocytes against H2O2-induced oxidative stress. Our data indicate no anti-inflammatory, antioxidant, or neurotrophic effect of 10-H2DA in astrocytes undergoing inflammation or oxidative stress. The effect of IGF-1 inhibition by 10-H2DA on neuronal ketogenesis needs investigation.

1. Introduction

The incidence of neurodegenerative disorders and other age-related diseases has dramatically increased during the last few decades due to the increased size of the aging population [1,2]. The widespread global pandemic of coronavirus disease 2019 (COVID-19) has been associated with multiorgan damage, including the central nervous system (CNS). CNS damage in acute COVID-19 patients manifest in the form of confusion, depression, anxiety, impaired memory, and insomnia [3]. Recovering patients experience persistent symptoms several months following hospital/ICU discharge [3,4]: depression (in up to 30% of patients) [5], sleep disorders (in up to 100% of patients), post-traumatic stress disorders (in up to 32% of patients) [3], and mild to moderate cognitive impairment (in up to
81% of patients) in patients who were cognitively intact before contracting COVID-19 [6,7]. Steroids are reported to foster tissue damage in COVID-19 patients [8]; mania and psychosis induced by steroids have been reported in a few COVID-19 patients [3]. In addition, the cytokine storm associated with COVID-19 is to blame for the inflammatory reactions and tissue damage that accompany COVID-19 infection [8–10]. Although presence of the virus causing COVID-19 in neurons does not cause neurodegeneration [1], evidence supports cytokine involvement in COVID-19-related neuropsychiatric disorders [1,7].

Neuroinflammation, which embraces increased levels of cytokines in the CNS, is a physiological response of brain cells to aging and pathological conditions, e.g., disease genes, injury, or infection [2,11]. Cytokines induce blood–brain barrier disintegration allowing increased passage of cytokines from circulation into the brain, which exaggerates central inflammation [1,2]. Excessive and uncontrolled neuroinflammation induces mitochondrial impairment and cellular stress, which contribute to protein misfolding and aggregation, neuronal damage, and the development of neurodegenerative disorders [1,12–14].

Lipopolysaccharide (LPS), a bacterial-derived toxin that crosses the blood–brain barrier, potently activates the innate immune system to induce neuroinflammation, neurotoxicity, and neurogenic drop [2,15,16]. LPS targets the electron transport chain of mitochondria resulting in mitochondrial permeability, increased production of free radicals e.g., nitric oxide species (NOS) and reactive oxygen species (ROS), diminished cellular antioxidant capacity, and heightened apoptosis [2,17]. However, the nature of the neuroinflammatory response is quite dynamic, and it does not always end with neurogenic loss; in vivo, a single LPS challenge is reported to cause a late proinflammatory response characterized by activation of microglia and astrocytes, increased levels of interleukin (IL)-6, and diminution of hippocampal neurogenesis. Furthermore, repeated intermittent injections of LPS did not elicit a late proinflammatory response or affect neurogenesis despite persistence of astrocytic activation [18].

Astrocytes, the main non-neuron brain cells that orchestrate the neurogenic microenvironment, respond to inflammatory signals in order to maintain homeostasis and repair tissue damage [2]. Reactive astrogliosis is a condition that involves cellular, molecular, and functional alterations that affect astrocytes as they respond to inflammatory stimuli [19]. The degree of astrogliosis depends on the severity of the insult; mild reactive astrogliosis involves cellular hypertrophy and increased expression of proinflammatory cytokines, while severe inflammatory processes induce cell proliferation and scar formation [19,20].

The levels of neurotrophic factors expressed by astrocytes change in response to neuroinflammation [12,21]. One of the main astrocyte-derived protective factors that increase during inflammation is glial cell line-derived neurotrophic factor (GDNF). GDNF is a survival factor that exerts nutritional and protective effects both in the CNS and in the periphery [21,22]. Astrocytic insulin growth factor-1 (IGF-1) acts as an anti-inflammatory molecule that can reduce astrocytes’ immune-mediated response to inflammatory stimuli, and it lowers their expression of proinflammatory cytokines [20,23]. Unlike GDNF, neuroinflammation is associated with a reduction in IGF-1 expression in astrocytes. Astrocytic IGF-1 deficiency during inflammation is a direct effect of mitochondrial oxidative stress induced by inflammatory stimuli such as LPS, which can be reversed by treatment with antioxidants (e.g., glutathione and N-acetylcysteine) [24]. In addition, proinflammatory cytokines that increase during inflammation interfere with insulin/IGF-I receptor coupling in astrocytes [25]. On the other hand, IGF-I downregulation is associated with improvement of peripheral tissue sensitivity to insulin and enhanced survival (long lifespan) [13,26].

Royal jelly (RJ) is a bioactive natural bee product that exhibits various pharmacological activities. Lipids constitute 7–18% of the RJ content. 10-hydroxy-trans-2-decenoic acid (10-H2DA), also known as RJ acid or queen bee acid, constitutes the vast majority of RJ lipid content (0.75% to 3.39%) [27]. 10-H2DA is a unique medium-chain unsaturated fatty acid that exists only in RJ, and it represents one of its main bioactive components [12,15]. 10-H2DA has been reported to increase neurogenesis—but inhibit gliogenesis—from neural
stem/progenitor cells, promote growth of cultured neurons, protect neurons against hypoxia, and decrease depressive and anxiety-like behaviors in both unstressed and stressed mice [2,26,27]. The effect of 10-H2DA on the brain has been investigated mainly in neurons, whereas little is known about its performance in astrocytes. The current study examined the effect of 10-H2DA in cultured astrocytes with a focus on exploring its neurotrophic promoting properties and astrocytes’ functional response (expression of proinflammatory cytokine genes IL-1β, IL-6, and TNF-α) under LPS-induced neuroinflammation, as well as cellular viability under H2O2-induced oxidative stress.

2. Materials and Method

2.1. Cell Culture

Cortical astrocytes were isolated from 1 or 2 day old pups of Wistar rats (Japan SLC, Inc., Shizuoka, Japan) according to our previous reports [19,28]. In short, the dissected cerebral cortex was digested with papin (9 U/mL, Sigma Aldrich, St. Louis, MO, USA) and DNase I (200 U/mL, Tokyo chemical industry Co., Ltd., Tokyo, Japan) and shaken for 20 min in a water bath at 37 °C. The dissociated cortical cells were cultured in a medium of complete Dulbecco’s modified Eagle medium (DMEM, Thermo Fisher Scientific Inc. Waltham, MA, USA) containing 10% fetal bovine serum (FBS) and 1% penicillin–streptomycin (Gibco) inside a 75 cm² flask at 37 °C under humidified air containing 5% CO2 (Thermo Fisher Scientific, Waltham, MA, USA). After 6–10 days, the flask was shaken at 220 rpm for 1 h, and the medium was replaced with a fresh medium to remove microglia. Then, it was further shaken at 220 rpm for 24 h inside an incubator at 37 °C. After that, astrocytes were detached from the flask with 0.25% trypsin and reseeded in 24-well (for real-time PCR) or 48-well (for cell viability) plates at a density of 1 × 10⁵ or 2.0 × 10⁴ cells/well, respectively. Cells were left to adhere to the plates inside an incubator. Once cells reached a confluency level of 80%, they were pretreated with the assigned concentrations of 10-H2DA for the indicated duration (24 h or 3 h) and then stimulated with LPS (10 ng/mL) for 3 h. All experiments involving the anti-inflammatory effects of 10-H2DA were performed in triplicate. All experiments were performed in accordance with the Guidelines for Care of Laboratory Animals of the National Center of Neurology and Psychiatry, Tokyo, Japan (Approval number #2017019).

2.2. Pharmacological Treatment

LPS from E. coli O111 B4 (Sigma-Aldrich, St. Louis, MO, USA) was dissolved in sterile distilled water (1 mg/mL). LPS was applied to cultured astrocytes at a final concentration of 0.01, 0.1, 1, 10, and 100 ng/mL. A 100 µM stock solution of 10-H2DA (Tokyo Chemical Industry Co. LTD, Tokyo, Japan) was prepared in ethanol. The mixture was vortexed until the sample was completely dissolved; then, it was kept at −30 °C until use. Several doses of 10-H2DA (1, 3, 10, 30, and 100 µM) were treated 3 or 24 h prior to LPS or H2O2 treatment. Concentrations of 10-H2DA within these ranges were decided based on a former study [29]. Control cells were treated with media; ethanol was not used as vehicle.

2.3. Real-Time PCR

Following media aspiration from each well, the cell monolayer was washed once with cold Dulbecco’s phosphate-buffered saline (DPBS), and total RNA was extracted with TRI Reagent® (Molecular Research Center, Inc., Cincinnati, OH, USA) according to the manufacturer’s protocol. The RNA concentration in each sample was measured by NanoDrop spectrophotometer (DeNovix DS-11, Scrum Inc., Cambridge, MA, USA), and samples were stored at −80 °C until use. cDNA synthesis was performed using SuperScript® VIRO™ cDNA synthesis kit (Thermo Fisher Scientific, Waltham, MA, USA). Real-time PCR was performed using StepOne Plus (Applied Biosystems, Carlsbad, CA, USA) with Thunderbird SYBR qPCR Mix (Toyobo, CO., Ltd., Osaka, Japan). Target mRNAs were amplified using each pair of gene-specific primers for IL-1β, IL-6, TNF-α, brain-derived neurotrophic factor (BDNF), GDNF, and IGF-1. The mRNA levels were normalized.
relative to the glyceraldehyde-3-phosphate dehydrogenase mRNA level of each sample, and the relative expression levels of all genes were calculated.

2.4. Cell Viability

Astrocytes treated with 10-H2DA (100 µM) for 3 and 24 h or 10-H2DA (10 µM) for 24 h were challenged with H2O2 (200 µM) (Fujifilm Wako, Osaka, Japan) for 3 h. Then, a 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyltetrazolium bromide (MTT, Nacalai Tesque, Tokyo, Japan) assay was performed according to a previous study [19]. In brief, the medium was replaced with MTT (0.5 mg/mL) in fresh medium and incubated for 1 h at 37 °C. Then, the resulting formazan salt was dissolved by isopropanol containing 0.04 N HCl, after which a microplate reader was used to measure the absorbance at 570 nm.

2.5. Statistical Analysis

Data are expressed as means ± SEM for the indicated number of independently performed experiments. Statistical comparisons of data were performed in SPSS IBM version 22 by one-way ANOVA with Tukey’s post hoc test. Significance was considered at probability values less than 0.05.

3. Results

Treatment with LPS was used to stimulate astrocytic inflammatory response, and it markedly increased the expression of cytokine genes. However, LPS at 10 ng/mL concentration significantly stimulated the expression of all proinflammatory cytokines (IL-1β, IL-6, and TNF-α) compared with the other concentrations (Supplementary Materials, Figure 1a–c). Therefore, the 10 ng/mL concentration was used in all subsequent LPS treatments.

![Figure 1](image-url) Effects of 10-H2DA on astrocytic expression of proinflammatory cytokines. (a–c) Astrocytes (n = 4) were treated with 10-H2DA alone (0–100 µM) for 24 h. (d–f) Astrocytes (n = 6) were treated with 10-H2DA (10 µM and 100 µM) for 24 h followed by LPS (10 ng/mL) for 3 h. Control values in (a–f) were obtained in the absence of LPS and 10-H2DA. The results are presented as means ± SEMs. Data were analyzed by one-way ANOVA with Tukey’s post hoc test; *p < 0.05 versus control cells. **: significance at 0.01, ***: significance at 0.001 compared with untreated cells. LPS treatment is indicated by + and absence of LPS is indicated by -.
3.1. The Effect of 10-H2DA on the Expression of Proinflammatory Cytokine Genes

To determine the optimal and the safest 10-H2DA concentrations to be used for further experiments, RT-qPCR was performed to examine the expression of proinflammatory cytokines after incubating astrocytes with 10-H2DA for 24 h in the absence of LPS. Treatment with different concentrations of 10-H2DA (0, 1, 3, 10, 30, and 100 µM) for 24 h did not cause any significant changes in the levels of proinflammatory cytokines except for low doses (3 µM), which significantly increased the expression of IL-1β (p = 0.011) compared with untreated control cells. According to the findings indicated in Figure 1a–c, two concentrations of 10-H2DA (10 µM and 100 µM) were chosen for subsequent experiments. Whereas LPS alone significantly enhanced the transcription of inflammatory-related genes, 10-H2DA pretreatment of LPS-stimulated cells exhibited no significant inhibition of the expression of IL-1β, IL-6, and TNF-α compared with solo LPS treatment, as shown in Figure 1d–f.

3.2. The Effect of 10-H2DA on the Expression of Neurotrophic Factors

Treatment with different concentrations of 10-H2DA (0, 1, 3, 10, 30, and 100 µM) for 24 h did not cause any significant changes in the levels of BDNF, GDNF, and IGF-1 except for one dose (3 µM), which tended to decrease the expression of IGF-1 compared with untreated control cells (p = 0.103) (Figure 2c). 10-H2DA (10 µM and 100 µM) decreased the expression of BDNF compared with LPS treatment alone. Astrocytes treated with LPS alone or with a combination of 10-H2DA (100 µM) and LPS demonstrated a significant increase in the mRNA expression of GDNF-related gene compared with untreated control cells (p = 0.000 and 0.005, respectively). However, GDNF expression levels were significantly lower in astrocytes pretreated with 10-H2DA (10 µM, p = 0.013) compared with cells treated with LPS alone; no significant difference was noted between both doses of 10-H2DA (p = 0.419). 10-H2DA (10 µM and 100 µM) pretreated astrocytes that were stimulated with LPS demonstrated a tendency toward decreased expression of IGF-1 compared with complete absence of treatment in control cells (p = 0.117 and 0.088, respectively).

Figure 2. Effects of 10-H2DA on astrocytic expression of neurotrophic factors. (a–c) Astrocytes (n = 4) were treated with 10-H2DA (0–100 µM) for 24 h. (d–f) Astrocytes (n = 6) were treated with 10-H2DA (10 µM and 100 µM) for 24 h followed by LPS (10 ng/mL) for 3 h. Control values in (a–f) were obtained in the absence of LPS and 10-H2DA. The results are presented as means ± SEMs. Data were analyzed by one-way ANOVA with Tukey’s post hoc test; * p < 0.05 versus control cells. ***, significance at 0.01, ****, significance at 0.001 compared with untreated cells. LPS treatment is indicated by + and absence of LPS is indicated by –.
3.3. The Effect of 10-H2DA on the Cell Viability of Astrocytes Undergoing Oxidative Stress

Treating astrocytes with H$_2$O$_2$ resulted in substantial cell death compared with control cells ($p = 0.000$) (Figure 3a,b). Treatment with 10-H2DA 10 µM and 100 µM for 24 h (Figure 3a) or 10-H2DA 100 µM for 3 h and 24 h (Figure 3b) did not protect astrocytes against the cytotoxicity of H$_2$O$_2$ compared with H$_2$O$_2$ control cells (all $p$-values > 0.05).

![Figure 3. Effects of 10-H2DA on cell viability. (a) Astrocytes ($n = 8$) were treated with 10-H2DA (10 µM and 100 µM) for 24 h. (b) Astrocytes ($n = 8$) were treated with 10-H2DA (100 µM) for 3 and 24 h. Cells were then exposed to H$_2$O$_2$-induced oxidative stress (100 µM) for 3 h. Control values in both (a) and (b) were obtained in the absence of H$_2$O$_2$ and 10-H2DA. Data represent the mean ± SEM (* $p < 0.05$ vs. H$_2$O$_2$ control, one-way ANOVA followed by Tukey’s post hoc test). H$_2$O$_2$ treatment is indicated by + and absence of H$_2$O$_2$ is indicated by -.

4. Discussion

According to our knowledge, 10-H2DA has not been used in astrocytes before. The study at hand is, therefore, the first to examine the anti-inflammatory, neurotrophic, and antioxidant effects of 10-H2DA in astrocytes. The findings indicate a high degree of complexity of 10-H2DA-mediated responses in astrocytes: (1) in the absence of LPS, low doses of 10-H2DA (3 µM) stimulated IL-1β expression and tended to decrease the transcription of IGF-1; (2) under inflammatory conditions, 10-H2DA had no inhibitory effect on LPS-induced inflammatory response but downregulated the expression of BDNF, GDNF, and IGF-1; (3) 10-H2DA did not protect astrocytes against H$_2$O$_2$-induced oxidative stress.

Astrocytes maintain homeostasis under normal physiological conditions by producing low levels of cytokines in response to byproducts of metabolic processes [30]. In the current study, low doses of 10-H2DA (3 µM) increased astrocyte expression of IL-1β in the absence of LPS. This finding is somewhat in accordance with results reported by Chen et al. (2016) noting increased expression of IL-6 in macrophages treated with low doses of 10-H2DA [31]. In line, small amounts of a synthesized derivative of RJ lipids known as 4-hydroperoxy-2-decenoic acid ethyl ester (HPO-DAEE) significantly prevented neuron death induced by 6-hydroxydopamine via a mechanism that involved stimulating ROS production, which resulted in activation of Nrf2, a pathway that masters the production of antioxidant enzymes [32]. We can, therefore, argue that, under normal physiological conditions, low doses of 10-H2DA may represent a nonpathogenic insult that might stimulate astrocytes to produce cytokines as an attempt for neuronal protection.

In the current study, 10-H2DA acid had no inhibitory effect on LPS-induced cytokine expression in astrocytes, which is consistent with findings reported in several former studies. 10-H2DA increased TNF-α expression and inhibited the mRNA expression of IL-10, an anti-inflammatory cytokine that can suppress immune response, in LPS-challenged RAW264.7 macrophages compared with single LPS treatment [31]. Similarly, 10-H2DA had no inhibitory effect on LPS-stimulated IL-6 production (unpublished data cited in [33]), as well as LPS-induced interferon (IFN)-β production, IFN regulatory factor-1 induction, and IFN-stimulated response element activation, which are required for NOS induction [34,35]. 10-H2DA did not protect neurons against 6-hydroxydopamine-induced cell death [32].
Taken together, our results, as well as those of previous studies, imply that 10-H2DA might not suppress neuroinflammation. Nonetheless, challenging astrocytes with LPS has been indicated as a neuroinflammation model of depression [24], while oral and intraperitoneal daily administration of 10-H2DA decreased depressive and anxiety-like behaviors in mice [36,37]. Thus, these reports suggest that the mechanism underlying the antidepressant effect of 10-H2DA does not involve suppressing neuroinflammation or reducing astrocytic activation. On the other hand, 10-H2DA at a concentration of 4 mM was reported to inhibit cytokines and activate forkhead box O (FOXO) transcription factor 1-mediated autophagy in LPS-challenged microglia [38]. Because that concentration was much higher than all concentrations used in the current study, the lack of effects of 10-H2DA on inflammation may be because the used concentrations of 10-H2DA might not be physiologically relevant.

In this study, 10-H2DA (3 µM) tended to increase IGF-1 under noninflammatory conditions. However, 10-H2DA downregulated the mRNA expression of IGF-1 in LPS-treated astrocytes (though not approaching significance). Downregulation of IGF-1 increases insulin sensitivity [13,26], which is likely to improve astrocytic glucose metabolism under normal conditions. The opposite may not be true for activated cells, which may have limited capacity to oxidize glucose metabolites secondary to pyruvate dehydrogenase inhibition [39]. Reduced insulin signaling promotes lifespan by blocking phosphatidylinositol (3,4,5)-triphosphate (PIP3) production, resulting in inhibition of PI3K and AKT kinase activity and blockage of FOXO phosphorylation, permitting FOXO proteins to remain in the nucleus, which facilitates the transcription of genes that encode antioxidant enzymes [39]. 10-H2DA is reported to expresses protective effects in LPS-treated microglia via FOXO1-mediated stimulation of autophagy [38]. It also demonstrated a lifespan-extending activity in Caenorhabditis elegans nematodes via IGF-1 downregulation, which is associated with the modulation of dietary restriction signaling [26]. Short-chain fatty acids similar to 10-H2DA are reported to alter mitochondrial respiratory chain in human astrocytes without lowering intracellular ATP levels or activating the energy sensor AMP-activated protein kinase. As a result, the rates of astrocytic ketogenesis increased 2.2-fold compared with control cells. Such modulation of astrocyte metabolism may activate shuttle systems that supply neighboring neurons with lactate and ketone bodies as a basic form of fuel [40]. Ketone bodies (e.g., d-β-hydroxybutyrate) extend lifespan by mimicking calorie restriction, and the metabolism of ketone bodies modulates the redox potential of the NADP antioxidant system, a terminal destructor of free radicals [39]. Therefore, 10-H2DA-induced reduction of IGF-1 in activated astrocytes may empower mitochondria, possibly leading to increased lifespan of these cells and their surrounding neurons. Moreover, altered mitochondrial metabolism creates a degree of cellular stress, which is associated with increased production of IL-6; IL-6 stimulates the release of other cytokines [41]. Therefore, it is likely that 10-H2DA treatment might mimic the effect of repeated LPS treatment, which prevents the development of a late proinflammatory response and associated neurons loss [18]. Nevertheless, more investigations are needed to examine the feasibility of such scenarios.

In the present study, use of 10-H2DA in unchallenged astrocytes had no effect on GDNF. Treatment with LPS alone significantly increased the expression of GDNF compared with untreated control cells, which is consistent with a former study [21]. Meanwhile, cells treated with both 10-H2DA and LPS had significantly lower GDNF levels (10-H2DA 10 µM) than cells treated with LPS alone. Despite the fact that GDNF is a survival factor that protects neurons during inflammation, a recent review indicates that GDNF is a strong promoter of glial proliferation and migration—an effect that is associated with glioma development [22]. Furthermore, severe neuroinflammation is associated with astrocytic proliferation [20]. Therefore, our finding indicates that moderate doses of 10-H2DA (10 µM) may finetune the expression of GDNF during neuroinflammation in a fashion that promotes its contribution to neurons survival and prevents astrocytic proliferation and migration. It seems that BDNF is less likely to be involved in the therapeutic activities of 10-H2DA in activated astrocytes; its levels dropped considerably in LPS-challenged cells.
that were pretreated with 10-H2DA (10 µM and 100 µM) compared with LPS alone. It is not clear why such a reduction in BDNF occurred.

Reports on the antioxidant properties of 10-H2DA are mixed. 10-H2DA was reported to prevent cellular death and increase properly polarized mitochondria in neurons challenged with glutamate and hypoxia compared with untreated controls [37]. On the contrary, Inoue et al. (2018) indicated that lipids of RJ (10-H2DA, 10-hydroxydecanoic acid, and sebacic acid) failed to counteract 6-hydroxydopamine-induced cellular death in human neuroblastoma SH-SY5Y cell cultures. However, one of their derivatives, HPO-DAEE, significantly prevented cell death and stimulated the production of antioxidant enzymes such as heme oxygenase-1 [32]. Our data revealed no antioxidant effect of 10-H2DA against H$_2$O$_2$-induced cell death, which is consistent with the results of Inoue et al. (2018). It is likely that 10-H2DA induced mitochondrial impairment [40], which is associated with increased cellular stress [41], at least during the acute phase, before a condition of cellular accommodation would take place. Such effects would promote the depletion of IGF-1 receptors in astrocytes, leading to further structural and functional distortions of mitochondria and increased mitochondrial ROS production, which may render astrocytes more sensitive to H$_2$O$_2$-induced cytotoxicity [42].

5. Conclusions

Our findings indicate that 10-H2DA may not directly alleviate neuroinflammation nor counteract oxidative stress in activated astrocytes. However, it may modulate astrocytic metabolism and prevent the development of a late inflammatory response and associated neurogenic loss. It also might play a role in finetuning the expression of GDNF under inflammatory conditions.
