Abstract: Using steady-state luminescence measurements, the luminescence spectra of Ce 3+, Pr 3+, Nd 3+, Sm 3+, Eu 3+, Dy 3+, Er 3+ and Yb 3+ for the agrellite sample from the Kipawa River region have been measured. The emission spectra of Eu 3+ and Dy 3+ next to those of Sm 3+ and Pr 3+ have been measured for characteristic excitation conditions. The most efficient luminescence activator in the studied sample was Ce 3+. This ion was also a sensitizer of Pr 3+, Sm 3+, Eu 3+, and Dy 3+ luminescence.

Keywords: agrellite; lanthanide ion; energy transfer

1. Introduction

Agrellite is a rather rare mineral and is usually found in pegmatite lenses and pods or in mafic gneisses in a regionally metamorphosed agpatic alkali rock complex. It occurs with eudialyte, britholite, aegirine, as well as miserite, vlasovite, calcite, fluorite, clinohumite, gittinsite, norbergite, zircon, bixbyte, phlogopite, galena, and quartz. The most known localities of it are the Sheffield Lake complex, Kipawa River, Villedieu Township, Quebec (Canada), Dara-i-Pioz massif, Alai Range, Tien Shan Mountains (China), (Tajikistan), the Murun massif, southwest of Olekminsk, Yakutia, (Russia) and Wausau complex, and finally, Marathon Co. in Wisconsin (USA). Among the minerals from the Kipawa River complex, only britholite, fluorite, calcite, miserite, and zircon are predisposed to exhibit fluorescence from lanthanide ions. However, no such reports are known so far. The knowledge of agrellite luminescence comes from websites only [1,2,3], and from the Gorobets and Rogojine review book [4]. According to these sources, agrellite has a dull pink color or a bright pink color under shortwave ultraviolet (SW UV) or longwave ultraviolet (LW UV, respectively. The following emission centers have been observed [4]: Ce 3+, Dy 3+, and Sm 3+ for samples from the Kipawa River; Fe 3+, Mn 2+, Eu 2+, and presumed Nd 3+ for samples from the Yakutia; and of Ce 3+ and Mn 2+ for specimens from the Dara-i-Pioz. The latest results of spectroscopic investigation of agrellite samples from Dara-i-Pioz (Tajikistan) and Murun massif (Russia) shows luminescence from Ce 3+ and EPR spectra of Mn 2+ [5].

An attempt was also made to synthesize sodium calcium silicate with an initial composition such as agrellite [6]. These materials were doped with Mn 2+ (1%, 2%, and 3%), Ce 3+ (0.5%), and Tb 3+ (4%), but as a result of synthesis, multiphase nanoparticles composed of wollastonite 2M CaSiO 3, devitrite Na 2CaSi 3O 8, and cristobalite SiO 2 was formed.

The current paper presents the preliminary results of a study of the luminescence properties of agrellite NaCa 2Si 4O 10F specimens from the Kipawa Alkaline Complex, Quebec, Canada.

Agrellite crystallized in triclinic, space group P(−1), and unit cell parameters are: a = 7.759 (2) Å, b = 18.946 (3) Å, c = 6.986 (1) Å, α = 89.88°, β = 116.65°, γ = 94.34°, Z = 4 [7]. All atoms in the agrellite
lattice are present in general positions and the Wyckoff site of all atoms is denoted as 2i. The crystal structure of agrellite consists of two different NaO₈ distorted cubes polyhedra, two CaO₅F octahedra (hereinafter referred to as Ca1B and Ca2A), and two CaO₆F₂ polyhedra (named as Ca1A and Ca2B) coupled with two different SiO₂₀ chains [7]. The mean of Ca–O and Ca–F distances are smaller for CaO₅F octahedra and equal for Ca1B and Ca2A, respectively 2.381 Å, 2.192 Å, 2.367 Å, and 2.201 Å than CaO₆F₂ and equal for Ca1A and Ca2B, respectively 2.574, 2.402, 2.615 Å and 2.454 Å (Figure 1a,b).

2. Materials and Methods

The agrellite sample studied here takes the form of fine lath-shaped aggregates measuring from a few to over 100 mm in length. It has a greenish-white color (Figure 2a) which changes to lavender-pink under mid UV (Figure 2b).

![Figure 1](image1.png)

Rare earth elements (REE) concentrations in the studied agrellite crystal were measured by the ISP-MS method at ACMA Lab (Canada), and the results are listed in Table 1. Steady-state fluorescence measurements for ions shown in the chemical analysis were performed using a Jobin-Yvon (SPEX) spectrofluorimeter FLUOROLOG 3-12 (Jobin-Yvon, Grenoble, France SPEX at
room temperature using a 450 W xenon lamp, a double-grating monochromator, and a Hamamatsu 928 photomultiplier (Hamamatsu Photonics, Shizuoka, Japan). The wavelength range for emission and excitation spectra was from 250 to 900 nm, and the resolution no lower than 1 nm. For such conditions, the emission and excitation spectra of Ce³⁺, Pr³⁺, Sm³⁺, Eu³⁺, Dy³⁺, and Er³⁺ in the UV–Vis range were recorded. The emission spectra of Nd³⁺, Yb³⁺, and Er³⁺ also in the NIR range were measured utilizing a Dongwoo Optron DM711 monochromator (MaeSan-Ri, Opo-Eup, Gwangju-Si, Gyeonggi-Do, Korea) coupled with a Hamamatsu 928 photomultiplier (Hamamatsu Photonics, Shizuoka, Japan), and an InGaAs detector (Hamamatsu Photonics, Shizuoka, Japan) depending on the spectral region. An InGaAs diode laser (Appolo Instruments, Irvine, USA) emitting infrared radiation at 975 nm and an AlGaAs diode laser (CNI, Changchun, China) emitting at 808 nm were used as continuous wave excitation sources.

3. Results

In the studied agrellite specimen, the minimum content of lanthanide ions as a potential luminescence activator can be estimated as 1.0 % (Table 1). If the distribution of these ions is uniform, then these ions are present in every 2.5 unit cell. The maximum distance among 4f ions is not less than 17.5 Å and not more than 47.25 Å.

Using steady-state fluorescence measurements, the emission of the following lanthanide ions were measured: Ce³⁺, Pr³⁺, Nd³⁺, Sm³⁺, Eu³⁺, Er³⁺, and Yb³⁺. Despite the significant Mn content, the emission spectra of Mn²⁺ were not measured. Unlike the [4] data, no emission from Fe³⁺ was obtained.

3.1. Nd³⁺, Yb³⁺, and Er³⁺ Luminescence

The emission of Nd³⁺ was measured as a group of three multiplets (Figure 3). The most intense was measured at 1046, 1060, 1064, 1078, and 1092 nm and corresponds to the 4F₃/2 → 4I₁₁/₂ transition. Another group of lines at 879, 885, 893, 905, and 917 nm is associated with the 4F₅/2 → 4I₇/₂ transitions and the last with lines at 1313, 1335, and 1340 nm with the 4F₃/2 → 4I₉/₂ transitions. The emission spectrum of Yb³⁺ was not very intense (inset of Figure 3) and band 979 nm corresponds to the transition 2F₅/2 → 2F₇/₂.
It was expected that the measurement of distinct emission lines of Er$^{3+}$ would be possible due to the significant content of this ion and its high luminescence efficiency. However, the emission bands of Er$^{3+}$ corresponding to the $^4F_{9/2} \rightarrow ^4I_{15/2}$, $^4S_{3/2} \rightarrow ^4I_{15/2}$ and $^4I_{13/2} \rightarrow ^4I_{15/2}$ transitions and usually measured at a 500–600 nm range were not clearly visible for steady-state luminescence measurements using a xenon lamp excitation, contrary to time-resolved measurements [8]. It has previously been verified [9] that for steady-time measurements using a xenon lamp, the most convenient excitation for Er$^{3+}$ is $\lambda = 377$ nm. However, for the studied agrellite specimen, only a weak emission band at 543 nm was measured (Figure 4). In the NIR range, the distinct emission band at 1533 nm (1554 nm, 1512 nm, and 1488 nm) was measured as a result of the $^4I_{13/2} \rightarrow ^4I_{15/2}$ transition (Figure 5). Using laser excitation, emission bands of $^2H_{11/2} \rightarrow ^4I_{15/2}$, $^4S_{3/2} \rightarrow ^4I_{15/2}$, and $^4F_{9/2} \rightarrow ^4I_{15/2}$ transitions were also obtained (inset in Figure 5). However, the intensities of these bands at 520 and 550 nm were very weak, not only in comparison with the Er$^{3+}$ emission in the NIR range but also with the Sm$^{3+}$ and Pr$^{3+}$ emission lines, although the samarium or praseodymium concentration was not much higher than the Er content (Figure 6).
Figure 4. Photoluminescence spectra of Er$^{3+}$ from the agrellite sample.

Figure 5. Emission spectra of Er$^{3+}$ from agrellite samples measured under laser excitations.
3.2. Ce$^{3+}$ Fluorescence

The cerium content in the studied agrellite sample was high. Electric-dipole 4f-5d transitions are even and spin allowed with the oscillator strength at half-width and short luminescence decay time. Cerium Ce$^{3+}$ is often added to synthetic crystals because of its well-known properties as an efficient sensitizer of luminescence. Luminescent materials doped with Ce$^{3+}$ can efficiently absorb excitation energy. A very intensive emission band at 388 nm has been measured (Figure 7). The zero phonon line (ZPL) position was designated in the point of spectral overlap of the excitation and emission curves, i.e., at $\lambda = 337$ nm (29,673 cm$^{-1}$). The Stokes shift $\Delta S$, as the energy difference between absorption/excitation and emission maxima of transition between the lowest 5d and the 4f ground states, is equal to 1567 cm$^{-1}$. This value is not very high, probably owing to the high coordination number around Ce$^{3+}$ and the long Ca–O distance [10,11]. For the lowest Raman frequency of agrellite 331 cm$^{-1}$, the Huang-Rhys parameter $S$ is equal to $S = 2.8$, so electron-phonon coupling may be recognized as intermediate.
Figure 7. Photoluminescence spectra of Ce\(^{3+}\) in agrellite sample.

On the excitation spectra, two bands at 284 nm and 321 nm were recorded, so the crystal-field splitting \(10 Dq\) of 5d level was estimated as 4059 cm\(^{-1}\). The upper excited level of Ce\(^{3+}\) is T\(_{2g}\) and the lower is E\(_{g}\). The \(10 Dq\) parameter for Ce\(^{3+}\) usually has a value in the 5,000–10,000 cm\(^{-1}\) range. For the studied crystal it was slightly smaller because the Ca–O length in agrellite is larger than in other Ca–minerals, for example fluor-apatite. The emission band of Ce\(^{3+}\) is nearly symmetric, although it was fitted to two Gaussian components with maxima at 28,023 cm\(^{-1}\) and 25,819 cm\(^{-1}\) (\(R^2 = 0.998\)) that can be discerned, (Figure 8), which correspond to the transition terminated on the \(^2F_{5/2}\) and \(^2F_{7/2}\) levels.
The intensity of the Ce\(^{3+}\) emission band at 388 nm measured for \(\lambda_{\text{exc}} = 284\) nm was almost 1.5 times higher than those observed for \(\lambda_{\text{exc}} = 321\) nm, despite the power of the xenon lamp is lower at \(\lambda = 284\) nm than at 321 nm. This may indicate that a significant part of the excitation energy at \(\lambda_{\text{exc}} = 321\) nm in the studied mineral transferred to other luminescence centers.

In [5] for the agrellite sample from Dara-i-Pioz, the emission and excitation spectra of Ce\(^{3+}\) have been presented. The Ce-content in this sample was 1160–1263 ppm, distinctly less than for the Kipawa River (Table 1). The emission band of Ce\(^{3+}\) was measured at 370 nm as a rather symmetrical band, while on the excitation spectrum, the following bands have been measured: 190, 220, 245, 281, and 317 nm. The differences in emission and excitation bands for the sample from Dara-i-Pioz (Tajikistan) and the Kipawa River are certainly due to the change in the Ce–O bonding length in both samples. It can be concluded that the crystal-field strength for the Kipawa River specimen is less than for the sample from Dara-i-Pioz. The possibility of Ce\(^{4+}\) presence and Ce\(^{4+}\) charge transfer bands on the absorption spectrum at 400 nm, which may be due to the gray color of agrellite crystals, was also assumed [5].

For the studied agrellite sample, the energy transfer between Ce\(^{3+}\) and Dy\(^{3+}\), Eu\(^{3+}\), Sm\(^{3+}\), and Pr\(^{3+}\) were found. Energy transfer in phosphors with sensitizer-activator ion pairs means that part of the excitation energy of the sensitizer ion transfers to activator ion through a non-radiative process and it subsequently enhances or generates the emission of the activator. The energy transfer among Ce\(^{3+}\) and other 4f ions is well known and used to synthesize phosphors with expected properties [12–18].

Gd\(^{3+}\) is another activator with intense absorption and emission lines in the UV range. Its excitation line is usually at 275 nm and corresponds to \({}^8S_{7/2} \rightarrow {}^4I_{5/2}\) transition, while emission could occur either from the \({}^4I_{5/2}\) or the \({}^6P_{5/2}\) level as a 312 nm band. The Gd\(^{3+}\) emission was rarely measured for mineral samples. However, the Gd\(^{3+}\) luminescence was found in some scheelite, anhydrite, apatite, and fluorite specimens [19]. Moreover, it was found for CaF\(_2\) [19] that due to energy transfer \(({}^4I_{5/2} \rightarrow {}^6P_{5/2})(\text{Gd}^{3+}) \rightarrow ({}^2F_{5/2} \rightarrow {}^2H_{5/2})(\text{Pr}^{4+})\), the emission at 275 nm is weakened, whereas at 312 nm it is enhanced. After using laser induction [4], time-resolved measurements of the Gd\(^{3+}\) fluorescence for zircon, anhydrite, and hardystonite have been prepared. The energy transfer among Gd\(^{3+}\) and many
RE\textsuperscript{3+} have been analyzed [10–27]. For the studied agrellite sample, the energy transfer from Gd\textsuperscript{3+} to RE\textsuperscript{3+} could be excluded. The validity of this thesis is based on the fact that:

(a) for all substances known from existing literature, the GdO\textsubscript{3} content was about 25 mol\% or more.

(b) the excitation and emission lines of Gd\textsuperscript{3+} did not appear in the agrellite spectra at all, although certain narrow lines should be clearly visible.

3.2.1. Energy Transfer Ce\textsuperscript{3+}-Dy\textsuperscript{3+}

The intense emission of Dy\textsuperscript{3+} related to \textsuperscript{4}F\textsubscript{9/2} $\rightarrow$ \textsuperscript{4}H\textsubscript{13/2} transition at 575 nm was measured for the most suitable excitation at $\lambda = 438$ nm (solid olive line in Figure 9). However, for $\lambda_{\text{exc}} = 321$ nm, not only was Ce\textsuperscript{3+} emission at 388 nm measured, but so was a Dy\textsuperscript{3+} emission band (solid red lines in Figure 9), and luminescence intensity was stronger than for the previous excitation. Moreover, on the excitation spectrum at $\lambda_{\text{em}} = 575$ nm corresponded to the \textsuperscript{4}F\textsubscript{9/2} $\rightarrow$ \textsuperscript{4}H\textsubscript{13/2} transition (dash-dot olive line in Figure 9), while the excitation band at 321 nm prevails on the Dy\textsuperscript{3+} band. It appears that the Ce\textsuperscript{3+} excitation band overlapped on the Dy\textsuperscript{3+} 4\textsuperscript{f}\textsubscript{9-4}f\textsubscript{8}5\textsuperscript{d} broadband or that it is transferred to the 4K\textsubscript{15/2}, 17/2 excited Dy\textsuperscript{3+} level.

![Figure 9](image)

**Figure 9.** The photoluminescence spectra of Dy\textsuperscript{3+}, Sm\textsuperscript{3+}, and Pr\textsuperscript{3+} and Ce\textsuperscript{3+}. Solid lines—emission spectra: black—$\lambda_{\text{exc}} = 284$ nm, red—$\lambda_{\text{exc}} = 321$ nm, olive line—$\lambda_{\text{exc}} = 348$ nm. Dash-dot lines—excitation spectra: dark olive line—$\lambda_{\text{em}} = 575$ nm, black line—$\lambda_{\text{em}} = 388$ nm.

3.2.2. Energy Transfer Ce\textsuperscript{3+}-Sm\textsuperscript{3+}, Pr\textsuperscript{3+}, and Eu\textsuperscript{3+}

The efficient emission of Sm\textsuperscript{3+} and Pr\textsuperscript{3+} was also found for agrellite crystal. In the spectral range of 550–700 nm, the emission lines of these two ions are located close to each other and are: at 562 nm and 569 nm as \textsuperscript{4}G\textsubscript{5/2} $\rightarrow$ \textsuperscript{4}H\textsubscript{5/2} transition of Sm\textsuperscript{3+}; at 601 nm and 607 nm of both Sm\textsuperscript{3+} \textsuperscript{4}G\textsubscript{5/2} $\rightarrow$ \textsuperscript{4}H\textsubscript{5/2} and Pr\textsuperscript{3+} \textsuperscript{4}D\textsubscript{2} $\rightarrow$ \textsuperscript{4}H\textsubscript{4} + \textsuperscript{4}I\textsubscript{0} $\rightarrow$ \textsuperscript{4}H\textsubscript{6} transitions; and at 648 nm mainly for Pr\textsuperscript{3+} transition \textsuperscript{3}P\textsubscript{0} $\rightarrow$ \textsuperscript{3}F\textsubscript{2}. As it was found earlier [9], the most convenient excitation for Sm\textsuperscript{3+} is the 399–402 nm line, while for Pr\textsuperscript{3+} it is 480 nm (Figure 10).
Figure 10. Excitation spectra characteristic for Pr$^{3+}$ (black line) and Sm$^{3+}$ (red line).

For $\lambda_{\text{exc}} = 402$ nm excitation, beside of Sm$^{3+}$ and Pr$^{3+}$ emission lines, the Eu$^{3+}$ emission at 613 nm attributed to transition $^5D_0 \rightarrow ^7F_2$ have been measured as well (Figure 11).

Figure 11. The photoluminescence spectra of Pr$^{3+}$, Sm$^{3+}$, and Eu$^{3+}$ in agrellite. Emission spectrum measured at $\lambda_{\text{exc}} = 402$ nm excitation—magenta line, excitation spectrum at $\lambda_{\text{em}} = 613$ nm—blue line, excitation spectrum at $\lambda_{\text{em}} = 601$ nm—red line, and excitation spectrum at $\lambda_{\text{em}} = 648$ nm—black line.
No emission of Eu$^{2+}$ was found. The emission of Eu$^{3+}$ as a characteristic line at 613 nm was obtained for the most convenient excitation $\lambda_{exc} = 393$ nm (Figure 12). However, this excitation also caused Sm$^{3+}$ and Pr$^{3+}$ emission.

![Figure 12. Excitation and emission spectra of Eu$^{3+}$ in agrellite.](image)

Under excitation $\lambda_{exc} = 321$ nm, not only the emission of Dy$^{3+}$ (574 nm) but also of Sm$^{3+}$ and Pr$^{3+}$ (562 nm, 569 nm, 601 nm, 607 nm), was measured (Figure 9). On the excitation spectra monitored at 562 nm, not only the most convenient bands for Sm$^{3+}$ (and Pr$^{3+}$) were measured but an intense band of Ce$^{3+}$ was recorded too. In the excitation spectra of Sm$^{3+}$, Pr$^{3+}$, and Eu$^{3+}$, the Ce$^{3+}$ band at 321–323 nm always appeared and it was intense. (Figure 13). This same effect has been measured when luminescence was excited into the Ce$^{3+}$ emission band, i.e., 388 nm (Figure 14).
The presence of the Ce$^{3+}$ excitation band in the PLE spectrum of Dy$^{3+}$, Sm$^{3+}$, Pr$^{3+}$, and Eu$^{3+}$ indicated the occurrence of Ce$^{3+} \rightarrow (\text{Dy}^{3+}, \text{Sm}^{3+}, \text{Pr}^{3+}, \text{and Eu}^{3+})$ energy transfer process. Upon UV irradiation, electrons from the $^2F_{5/2}$ ground state of Ce$^{3+}$ are excited into the 5d excited state. Some of these electrons return to the ground states ($^2F_{7/2}$ and $^2F_{5/2}$) of Ce$^{3+}$ ions, resulting in the violet-blue
emissions of Ce\(^{3+}\) due to the 5d \(\rightarrow\) 4f transition. At the same time, owing to the nonradiative resonant energy-transfer, a portion of excited electrons can be transferred into the \(^{4}\text{K}_{15/2,17/2}\) excited levels of Dy\(^{3+}\) and then relax, mainly as \(^{4}\text{F}_{9/2} \rightarrow ^{6}\text{H}_{13/2}\) transition. Similarly, another portion of excited electrons can be transferred into excited levels of \(^{4}\text{K}_{11/2}\) or \(^{3}\text{P}_{2}\) of Sm\(^{3+}\) or Pr\(^{3+}\) and subsequently, the electrons can relax to their ground levels.

4. Conclusions

In the studied agrellite crystal, the lanthanide ions form a complex arrangement of luminescence centers. The f-f emission of many ions has been distinctly excited by the excitation band of Ce\(^{3+}\). Generally, the mechanism of energy transfer from donor to acceptor ions can be attributed to an exchange interaction or electric multipolar interaction. The average distance \(R_c\) between the Ce\(^{3+}\) donors and Sm\(^{3+}\) or Pr\(^{3+}\) acceptors was estimated as a value according to the below equation where \(C\) is the total concentration of 4f\(^n\) ions in the studied sample, \(N\) is the coordination number, and \(V\) is the cell volume:

\[
R_c = \frac{3}{4\pi} \sqrt{\frac{V}{C \cdot N}}
\]

when this value was determined to be 19.38 Å and it is greater than 5 Å, the energy transfer process would take place via electric multipolar interaction. The direct confirmation of this conclusion could be obtained by measuring the decay lifetimes of Ce\(^{3+}\), Dy\(^{3+}\), Sm\(^{3+}\), and Pr\(^{3+}\) emissions, as well as the changes in luminescence intensities of these ions for samples containing their variable content. It is necessary to carry out measurements for other specimens of agrellite, differing in the content of these ions.

Contrary to the information on the website [3], the luminescence of Mn\(^{2+}\) has not been observed, although it was stated at 580 nm; similarly, no emission band of Eu\(^{2+}\) which was notified at 410 nm was observed. Additionally, the emission lines of Dy\(^{3+}\) at 478 nm or of Er\(^{3+}\) at 522 nm were not clear. It was observed that the measured emission spectra in the 400–560 nm range show intensive scattering of incident radiation not related to the effect of light reflection from the crystal surface. It can be assumed that it is due to the presence of numerous defects on \([\text{Si}_4\text{O}_{10}]^{4-}\) and will be confirmed after femtosecond excitation measurements.

Some differences have been observed between the emission spectra of agrellite specimens for various localities presented in [4] or [5] and our results. The main reason for these differences is certainly the difference in REE content, although the data contained in [1,2] are incomplete. The agrellite specimen from the Kipawa River studied in the current research contains more Ce and a comparable amount of Mn and Fe as a sample from Dara-i-Pioz, and it is more than the sample from Yakutia [5]. However, contrary to [1] but similar to [5], we did not measure the emission of Mn\(^{2+}\) as was stated for the specimen from Dara-i-Pioz, and also the emission of Fe\(^{3+}\)\(_{\text{tota}}\) and Eu\(^{2+}\) as was shown for the specimen from Yakutia. Compared to previous luminescence results for specimens from the Kipawa River [4], the emissions from Er\(^{3+}\), Pr\(^{3+}\), and Eu\(^{3+}\) were also measured in the current research.

The most important result of the present research is the demonstration of the phenomenon of effective energy transfer between Ce\(^{3+}\) as a donor and Pr\(^{3+}\), Sm\(^{3+}\), and Dy\(^{3+}\) as the acceptors. For this reason, a synthetic material based on agrellite, subsidized with the right amount of these ions, can be an efficient white light emitter.
