Abstract: Application of nanoparticles in aqueous base-fluids for intensification of absorption rate is an efficient method for absorption progress within the system incorporating bubble-liquid process. In this research, SO\textsubscript{2} and CO\textsubscript{2} were separately injected as single raising bubbles containing nanofluids to study the impact of nanoparticle effects on acidic gases absorption. In order to do this, comprehensive experimental studies were done. These works also tried to investigate the effect of different nanofluids such as water/Al\textsubscript{2}O\textsubscript{3} or water/Fe\textsubscript{2}O\textsubscript{3} or water/SiO\textsubscript{2} on the absorption rate. The results showed that the absorption of CO\textsubscript{2} and SO\textsubscript{2} in nanofluids significantly increases up to 77 percent in comparison with base fluid. It was also observed that the type of gas molecules and nanoparticles determine the mechanism of mass transfer enhancement by nanofluids. Additionally, our findings indicated that the values of mass transfer coefficient of SO\textsubscript{2} in water/Al\textsubscript{2}O\textsubscript{3}, water/Fe\textsubscript{2}O\textsubscript{3} and water/SiO\textsubscript{2} nanofluids are, respectively, 50%, 42% and 71% more than those of SO\textsubscript{2} in pure water ($k_{L_{SO_2-water}} = 1.45 \times 10^{-4}$ m/s). Moreover, the values for CO\textsubscript{2} in above nanofluids were, respectively, 117%, 103% and 88% more than those of CO\textsubscript{2} in water alone ($k_{L_{CO_2-water}} = 1.03 \times 10^{-4}$ m/s). Finally, this study tries to offer a new comprehensive correlation for mass transfer coefficient and absorption rate prediction.

Keywords: nanofluids; absorption intensification; mass transfer coefficient; bubble column

1. Introduction

Combustion of fossil fuels led to deforestation and global warming by the emission of acidic gases such as SO\textsubscript{2} and CO\textsubscript{2} into the environment [1]. Hence, in 1992, the United Nation Conference on Environment and Development offered a new strategy for reducing the emission of acidic and other greenhouse gases to below the standard level until 2000 [1]. Consequently, the governments should finance researchers and scholars to apply new methods and techniques to reduce the amount of CO\textsubscript{2} as well as the SO\textsubscript{2} produced from large-scale industries and sources [2–6].

In order to remove acidic gases from the natural gas, the scrubbing with the amine solution is the main process in the gas refineries. In addition, various techniques including physical and chemical absorption, membrane technology and adsorption methods are applied for the high CO\textsubscript{2}/SO\textsubscript{2} production industries such as metal forming plants and petrochemical companies [7–9]. One of new approaches for enhance the absorption process, is addition of nanomaterials to basefluids for obtaining novel solvent with ability to absorb gases efficiently [2,3,10,11]. This method were elucidated by several researchers due to its high efficiency, and it has received much more attention in recent years [12,13].

Krishnamurthy et al. fulfilled a comprehensive research on the application of nanoparticles for increasing of mass transfer rate within a basefluid environment. They revealed that Brownian motion...
of nanoparticles, leading to induce the micro-convections in nanofluids, has the most impact on mass transfer rate [14]. Ashrafmansouri et al. comprehensively studied previous research and reported an review to highlight the impacts of nanomaterials in heat and mass transfer processes [11]. They reported that much higher thorough studies are needed to disclose the impacts of main parameters including nanoparticles mean size and morphology on absorption rate by using nanofluids. They also exhibited that nanofluid reusing as well as absorption process modeling are the most important subjects for advancement of this technique. In addition, Kim et al. showed that mass transfer rate of ammonia is enhanced when a few nanoparticles are added to the basefluid. They exhibited that bubbles breaking by nanoparticles considerably enhances mass transfer through increasing interfacial area. They also reported that smaller bubbles were produced in nanofluid than in a base fluid, leading to intensification in mass transfer surface area [15].

Ma et al. declared that by adding CNTs to a basefluid, the localized micro-convection occurs due to the Brownian motion of nanotubes [16]. They reported that induced convection can intensify the ammonia molecular diffusion within the nanofluid. Moreover, they concluded that the grazing effect can be considered another mechanism enhancing the efficiency of NH3 by means of the bubble absorption process [16]. Absorption of gas molecules by means of the nanoparticle surfaces at the bubble interface and then removing the adsorbed gas components from the nanoparticles surface into the fluid is known as grazing effect [17]. Kang et al. also assessed the impact of Carbon nanotubes on gas absorption in a nanofluid [18]. They also revealed that the mass transfer rate of gaseous ammonia in 0.001 wt. % CNTs loaded in nanofluid was 20% higher than that of pure deionized water [18,19].

Numerous researchers have focused on the application of nanofluids as a potential absorbent for the removal of acidic gases [6,11,12,20–23]. Esmaeili-Faraj et al. exhibited that the removal rate of H2S enhanced up to 40% when 0.02 wt. % of EGO (Exfoliated Graphene Oxide) is added to deionized water as a basefluid. They showed that the main mechanism for enhanced absorption rate is the grazing effect [4].

Jung et al. performed an extensive research in which Al2O3 nanoparticles were scattered in methanol as with nanoparticles volume fractions range of 0.005–0.1 vol. % [24]. They observed that the maximum CO2 removal was 8.3% at 0.01 vol. % nanoparticles compared to the conditions that pure methanol was used as an absorbent. They concluded that the enhanced CO2 uptake is due to the mixing effect of Al2O3 nanoparticles, which were caused by the particle-laden flows induced by Brownian motion [24]. In addition, they observed that for the concentration above a critical value, insignificant Brownian motion can be seen since the inter-particle interactions declines this motion [24].

Darvanjooghi et al. studied the absorption of CO2 by means of Fe3O4/water nanofluid during the applied alternating and constant magnetic fields [3]. Their results declared that both CO2 solubility and mass transfer rate are increased when the strength of magnetic field is high. In addition, they found that the solubility of CO2 and its average molar flux into the nanofluid possess a maximum value by applying an AC magnetic field. Finally, they showed that with the increment of magnetic field strength, the mass diffusivity of carbon dioxide in the nanofluid and renewal surface factor increase, whereas the diffusion layer thickness diminishes.

Although, the impacts of different parameters on gas absorption, by means of nanofluids, are studied in previous works, there are no fully agreement and comprehensive results regarding the influence of nanoparticles types on mass transfer parameters in oxides nanoparticles loaded in nanofluids.

Thus, the aim of this study is to reveal the effect of different metal oxide nanoparticles on SO2 and CO2 mass transfer parameters in a single-bubble absorber. Hence, comprehensive experimental studies are done to investigate the molar flux, absorption rate, mass transfer coefficient and diffusivity coefficient. In addition, a new correlation encompassing nanofluid properties was developed in order to estimate mass transfer coefficients of the mentioned gases in nanofluids.
2. Materials and Methods

2.1. Materials

In this research, SiO$_2$ nanoparticles with the purity of 99.99 wt. %, Al$_2$O$_3$ nanoparticles with the purity of 99.98 wt. % and Fe$_2$O$_3$ nanoparticles with the purity of 99.92 wt. % were purchased from U.S. Nano Company, United State (see Table 1) to prepare water based nanofluids. In order to perform reverse titration for measuring the quantity of CO$_2$ and SO$_2$ dissolved in nanofluids, pure NaOH pellets (99.99 wt. %) and HCl with the purity of 37 vol. % were purchased from Merck Company, Germany. Moreover, phenolphthalein and methyl orange obtained from Merck Company, Germany were used as indicators for determination of the equivalent points. Deionized water was used for the preparation and dilution of nanofluids as well as washing the laboratory glassware. All chemical materials are used as received without further purification.

2.2. Apparatus

2.2.1. Nanofluid Preparation Instruments

In this study, the transmission electron microcopy (TEM) and dynamic light scattering (DLS) were used to estimate the size distribution of dry and dispersed metal oxides nanoparticles in deionized water, respectively. The TEM images of SiO$_2$, Al$_2$O$_3$ and Fe$_2$O$_3$ nanoparticles were obtained by using Hitachi, 9000 NA, Japan to characterize the size of nanoparticles and their agglomeration [25]. For preparing the sample of nanoparticles used in TEM analysis, a suspension of the nanoparticles dispersed in ethanol (0.001 wt. %) was sonicated by using an ultrasonic bath, Parsonic 30S-400W, 28 kHz, for 20 min and then was placed on the graphite surface. The samples were then put in a vacuum oven to remove the ethanol before being introduced into the TEM test device. DLS, Malvern, Zeta Sizer Nano ZS, United Kingdom, was applied to estimate the sizes of nanoparticles and the size distribution of the obtained metal oxides nanoparticles in deionized water [5,25,26]. The stability and surficial electrostatic charges of the metal oxides nanoparticles in deionized water were estimated by using Zeta Potential test (ELSZ-2000, Otsuka Electronics Co., Osaka, Japan). This analysis is a key indicator of the stability of metal oxides nanoparticles within deionized water [12]. Zeta potential accounts for the electrostatic charges on the surface of nanoparticles causing repulsive forces between dispersed particles. The negatively and positively larger magnitude of zeta potential exhibits a significant stability of nanoparticles in the basefluid, whereas a lower magnitude of maximum Zeta-potential declares the tendency of nanoparticles for agglomeration [27]. A Mass Flow Controller (MFC) model Brooks Instrument 1-888-554-flow, USA, was implemented for the injection of CO$_2$ and SO$_2$ gases into the nanofluids through the absorption apparatus. Furthermore, water based nanofluids were prepared by measuring and adding the required weight amounts of metal oxide nanoparticles. To do so, a precise electric balance (TR 120 SNOWREX, Taiwan) was implemented. A pH meter (PCE-PHD 1, PCE-Instruments holding, Southampton, UK) was used for recording the pH of solutions during the titration. Finally, an ultrasonic processor (QSONICA-Q700, NY, USA) was used in order to stop the agglomeration of SiO$_2$, Al$_2$O$_3$ and Fe$_2$O$_3$ nanoparticles, after they were under a mechanical ball-mill (YKM-2L, Changsha Yonglekang Equipment Co., Changsha, China) for grinding the clustered nanoparticles. A syringe-pump (Viltechmeda Plus SEP21S, manufactured in Vilnius, Lithuania) was...
also employed for injection of the titrant to the flask. Lastly, a magnetic stirrer (Model IKA-10038, Staufen, Germany) was used for stirring the solutions.

2.2.2. Experimental Set-Up

The experimental set-up contained a bubble column absorber filled with metal oxide nanoparticles loaded in nanofluids. A certain volume of CO$_2$ and SO$_2$ was injected into the nanofluid within the absorption column. Figure 1 exhibits the schematic diagram of a bubble column absorber that consists of a 1 m high and 16.2 mm diameter poly-methyl-meta-acrylate (PMMA) tube used as a semi-batch instrument to examine the absorption of acidic gases by means of nanofluids. In addition, in order to control the rate of gas absorption in nanofluids, a syringe-pump was used for the injection of the aforementioned gases through the absorber column. The gases were continuously injected into nanofluids in the absorber column with the constant flow rate of 500 mL/h in each experiment. The average bubbles diameter ranged from 6.9 to 7 mm, and the time for the rising of bubbles was found to be 2.3 s. Finally, in order to measure the concentration of gases in nanofluids in the reverse titration method, the injection of HCl solution into the discharged nanofluid was performed by means of the syringe-pump.

![Figure 1. Schematic diagram of experimental set-up.](image)

2.3. Methods

2.3.1. Nanofluid Preparation Procedure

At first, the nanoparticles were introduced to a ball-mill device for about 4 h to separate the agglomeration of nanoparticles. Then, water based nanofluids were prepared with the dispersing of 50 g SiO$_2$, Al$_2$O$_3$, and Fe$_2$O$_3$ nanoparticles in 1000 mL deionized water, separately, to produce the main suspension with the nanoparticles concentration of 5.0 wt. %, (equal to 50,000 mg/L). After adding the nanoparticles to deionized water, the suspensions were kept under stirring condition of 800 rpm for 5 h. Finally, the nanoparticles were dispersed in the basefluid by using the sonication process under three sequences of 20 min. The amplitude and cycle time of sonication were set on 70% and 0.5 s, respectively. Also for the preparation of other suspensions with different nanoparticle concentrations of 0.005, 0.01, 0.1, 1.0, and 5.0 wt. %, the stock solutions were diluted with further deionized water.
2.3.2. Experimental Procedure

Sample Analysis Procedure

The analysis for measuring the amounts of absorbed CO₂ and SO₂ in the nanofluids was carried out by using the reverse titration wherein the standard HCl and NaOH solutions were used as the titrant and reactant for producing Na₂CO₃ and Na₂SO₃, respectively [28]. Consequently, in order to determine CO₂ and SO₂ content by using the reverse titration, it is needed to convert H₂SO₃ and H₂CO₃ to Na₂SO₃ and Na₂CO₃, respectively, by the addition of a strong standard base. To do so, the nanofluids were discharged to the flask containing 15 mL of 0.1 M NaOH solution. The carbon dioxide and sulfur dioxide in the solution reacted with the sodium hydroxide and formed sodium bicarbonate or bisulfate as Equation (1) [5]:

\[
RO_2 + 2NaOH \rightarrow Na_2RO_3 + H_2O, \quad R = C(\text{Carbon}) \text{ or } S(\text{Sulfur})
\] (1)

The titration was then accomplished to neutralize the amount of remained NaOH, and then excess HCl (as a titrant) in the flask reacted with Na₂SO₃ and Na₂CO₃ during the titration according to the following reactions:

\[
Na_2RO_3 + HCl \rightarrow NaCl + NaHRO_3, \quad R = C(\text{Carbon}) \text{ or } S(\text{Sulfur})
\] (2)

\[
NaHRO_3 + HCl \rightarrow NaCl + H_2O + RO_2, \quad R = C(\text{Carbon}) \text{ or } S(\text{Sulfur})
\] (3)

According to Equation (2), the discharged samples were titrated with the standard acid solution, (0.1 M HCl), at first equivalent point. The titration with HCl then converted all the remained bicarbonate and bisulfate to SO₂ and CO₂ according to Equation (3). In this method, the difference of consumed HCl between two equivalent points represents the amount of CO₂ or SO₂ absorbed in the solution. Equation (4) was used for determining the value of absorbed gases by means of nanofluids [2,3,28]:

\[
C_{RO_2} = \frac{(V_2 - V_1) \times M}{V} \times 10^3
\] (4)

where \(C_{RO_2}\) is the absorbed CO₂ or SO₂ concentration in the nanofluids or deionized water (mol/m³), M is HCl molarity (mol/lit), and V is the volume of absorbent used in the column, (equal to 100 mL), in all experiments. \(V_1\) and \(V_2\) are the volumes (mL) of standard acid solution consumed for neutralizing bicarbonate and bisulfate to SO₂ and CO₂ at two equivalent points, respectively (Figures 2 and 3).

![Figure 2. Plot of pH and its differentiation versus volume of consumed titrant, (HCl), for the injection of 50 mL SO₂ through deionized water.](image-url)
In this research, the uncertainty of the experimentations was calculated by the errors of measurements for parameters, incorporating time of raising bubbles, volume of liquid for the titration method and pH of solutions. The time of raising bubbles was measured by using a digital chronometer with the maximum accuracy of ±0.01 s, the pH of discharged nanofluids was measured during the titration by a pH meter with the maximum accuracy of ±0.1, and the volumes of liquids were measured by laboratories glassware with the maximum accuracy of ±0.1. According to the literature [2,3], the relative uncertainty of final experimental results was calculated as follows [30,31]:

\[
U = \pm \sqrt{\left(\frac{\Delta V}{V}\right)^2 + \left(\frac{\Delta t}{t}\right)^2 + \left(\frac{\Delta pH}{pH}\right)^2} \tag{6}
\]

Consequently, by substituting the values in Equation (6) the relative uncertainty of the experimental results was found to be less than 5.2%.

Figure 3. Plot of pH and its differentiation versus volume of consumed titrant, (HCl), for the injection of 50 mL CO₂ through deionized water.

In this work, the molar flux of absorbed CO₂ and SO₂ was calculated by means of the CO₂ and SO₂ concentration in the nanofluid according to the following equation (Equation (5)) [2,3,28]:

\[
N_{\text{ave},\text{RO}_2} = \frac{C_{\text{RO}_2} \times V}{4\pi r_0^2 n} \times (\tau) \times 10^{-6} \tag{5}
\]

Here, \(N_{\text{ave},\text{RO}_2}\) is the average molar flux transferred from gas, (pure CO₂ or SO₂), to liquid phase (mol/m² s), \(\tau\) is the total gas-liquid contact time of bubbles passing through the nanofluids (s), which is equal to multiply of the bubbles number by raising time of one single bubble (2.3 s), \(n\) is the number of bubbles passes through nanofluids within the absorber column and \(r_0\) is the average bubbles radius (3.5 mm) that assumed to be constant at all experiments.

Measurement of Mass Transfer Parameters

In order to obtain the mass transfer coefficient and diffusivity of CO₂ or SO₂ in a water based nanofluid, a set of experiments were performed in which the aforementioned gases were separately injected at the bottom of the column within the volumes of 20, 25, 30, 35, 40, 45 and 50 mL. The mass transfer parameters were then calculated by obtaining the absorption of CO₂ and SO₂ as well as the implementation of the model suggested by Zhao et al. [29].

Uncertainty Analysis

In this research, the uncertainty of the experimentations was calculated by the errors of measurements for parameters, incorporating time of raising bubbles, volume of liquid for the titration method and pH of solutions. The time of raising bubbles was measured by using a digital chronometer with the maximum accuracy of ±0.01 s, the pH of discharged nanofluids was measured during the titration by a pH meter with the maximum accuracy of ±0.1, and the volumes of liquids were measured by laboratories glassware with the maximum accuracy of ±0.1. According to the literature [2,3], the relative uncertainty of final experimental results was calculated as follows [30,31]:

\[
U = \pm \sqrt{\left(\frac{\Delta V}{V}\right)^2 + \left(\frac{\Delta t}{t}\right)^2 + \left(\frac{\Delta pH}{pH}\right)^2} \tag{6}
\]

Consequently, by substituting the values in Equation (6) the relative uncertainty of the experimental results was found to be less than 5.2%.
3. Results and Discussion

3.1. Nanofluid Characterization

Figure 4 exhibits the TEM images of SiO$_2$, Al$_2$O$_3$ and Fe$_2$O$_3$ nanoparticles that used for the preparation of water based nanofluids. These images show that the diameter of SiO$_2$ nanoparticles ranged from 20 to 60 nm (Figure 4a), the diameter of Al$_2$O$_3$ nanoparticles ranged from 30 to 80 nm (Figure 4b) and the diameter of Fe$_2$O$_3$ nanoparticles ranged from 20 to 60 nm (Figure 4c). In addition, the results presented in Figure 4 exhibit that all metal oxides nanoparticles have a semi-spherical morphology that no considerable agglomeration was observed [32].

Figure 4. Transmission electron microcopy (TEM) images of (a) SiO$_2$, (b) Al$_2$O$_3$ and (c) Fe$_2$O$_3$ nanoparticles.
The results of DLS analysis for SiO$_2$, Al$_2$O$_3$ and Fe$_2$O$_3$ nanoparticles dispersed in deionized water exhibited that the mean diameter of nanoparticles for SiO$_2$ is 48.3 nm with Poly Dispersity Index, (P.D.I.), of 0.105 and the mean diameter of nanoparticles for Al$_2$O$_3$ and Fe$_2$O$_3$ is found to be 54.7 nm and 55.1 nm, respectively, with P.D.I.s of 0.145 and 0.138, respectively. These results confirm that the dispersion technique, which was used in this research, led to the well-dispersed nanoparticles diameter, with a narrow range of 48.3 to 55.1 nm. The results of this test indicate that the average size of nanoparticles is equal to that estimated by using TEM test declaring no significant agglomeration during the dispersion of nanoparticles in the basefluid.

Zeta-potential analysis can be implemented in order to quantify the stability of nanoparticles in the basefluid [33]. These results represent that nanofluids have high stability due to the fact that their zeta potential is lower than $-45$ mV [34]. In other words, the magnitude of the zeta potential determines the degree of electrostatic repulsion between similarly charged particles in colloidal dispersions. The large magnitude of the zeta potential for SiO$_2$/water, Al$_2$O$_3$/water and Fe$_2$O$_3$/water nanofluids ($-97.8$ mV for Al$_2$O$_3$/water, 100.2 mV for SiO$_2$/water and 79.5 mV for Fe$_2$O$_3$/water nanofluids) indicated high stability of nanoparticles representing high repulsive electrostatic forces [35].

3.2. Absorption

3.2.1. Maximum Absorption

Figure 5 shows the average molar flux of CO$_2$ into each of these three nanofluids: SiO$_2$/water, Al$_2$O$_3$/water or Fe$_2$O$_3$/water. The mass fraction of each metal oxides nanoparticle varies from 0.005 to 5 wt. %. The experimentations were repeated four times at a fixed mass fraction of metal oxides nanoparticles and the standard deviations are shown in this figure as the error bars. According to the results presented in this figure, the average molar flux of CO$_2$ increases about 21% with the increase of Al$_2$O$_3$ nanoparticles from 0.005 to 0.1 wt. % while the molar flux decreases for higher Al$_2$O$_3$ nanoparticles loads (0.1 to 5 wt. %). Moreover, the value of CO$_2$ molar flux increases about 45% when the mass fraction of SiO$_2$ nanoparticles increases from 0.005 to 0.01 wt. %. Moreover, for higher mass fractions of SiO$_2$ nanoparticles, a remarkable declination on CO$_2$ molar flux resulted. In addition, the value of CO$_2$ molar flux enhances about 16% when mass fraction of Fe$_2$O$_3$ nanoparticles enhances from 0.005 to 1 wt. %, and a declination of CO$_2$ molar flux resulted in the mass fraction range of up to 5 wt. %. Table 2 represents the mass fraction of nanoparticles where by the maximum value of CO$_2$ molar flux obtained. It can be concluded from this table that CO$_2$ absorption molar flux has a maximum value at 0.1, 0.01 and 1 wt. % for Al$_2$O$_3$/water, SiO$_2$/water and Fe$_2$O$_3$/water nanofluids, respectively. For all nanoparticles types, the nanoparticles intensify the micro-convections, producing larger mass transfer rate in comparison to pure basefluid; thus, initial increase in CO$_2$ absorption would be rationalizable with the aforementioned nanoparticles mass fractions. On the other hands, increasing a number of nanoparticles leads to enhance further the viscosity of nanofluids, thereby overcoming the nanoparticles micro-convection impacts together with diminishing the absorption of CO$_2$ within the nanofluids [4,12]. Furthermore, Figure 5 clearly exhibits that CO$_2$ absorption molar flux in metal oxides-based nanofluids is larger than that in deionized water for various nanoparticles mass loads.
were also repeated four times at a fixed mass fraction of each metal oxide nanoparticle, and the error bars express the standard deviation obtained from the measurements. According to the obtained experimentations were also repeated four times at a fixed mass fraction of each metal oxide nanoparticle, and the error bars express the standard deviation obtained from the measurements. According to the obtained results, the average molar flux of SO\textsubscript{2} enhances about 28\% with the Al\textsubscript{2}O\textsubscript{3} nanoparticles enhancement from 0.005 to 0.1 wt. \%, and for higher nanoparticles loads, a substantial decrease resulted in its molar flux. In addition, the value of SO\textsubscript{2} absorption rate into SiO\textsubscript{2}/water nanofluid increases about 32\% when the mass fraction of SiO\textsubscript{2} nanoparticles in deionized water increases from 0.005 to 1 wt. \%. After a further increase of mass fraction up to 5 wt. \%, the absorption of CO\textsubscript{2} declines. Moreover, the value of CO\textsubscript{2} molar flux increases about 26\% when mass fraction of Fe\textsubscript{2}O\textsubscript{3} nanoparticles increases from 0.005 to 0.1 wt. \%; and with a further increase of nanoparticles mass fraction from 0.1 to 5 wt. \%, the value of CO\textsubscript{2} absorption declines. According to the results presented in Table 2, the maximum molar flux of SO\textsubscript{2} can be obtained with the nanoparticles mass fractions of 0.1, 1 and 0.1 wt. \% for Al\textsubscript{2}O\textsubscript{3}/water, SiO\textsubscript{2}/water and Fe\textsubscript{2}O\textsubscript{3}/water nanofluids, respectively. Similar to the results achieved for CO\textsubscript{2} absorption, the addition of nanoparticles into the deionized water enhances the micro-convections and intensifies the mass transfer rate of SO\textsubscript{2} while increasing the nanoparticles load increases further the viscosity of nanofluids, declining the absorption rate of SO\textsubscript{2} into the nanofluids [4,12]. The results presented in this figure show that SO\textsubscript{2} absorption in metal oxides nanofluids is more than that in deionized water.

Figure 6 displays the average molar flux of SO\textsubscript{2} into each of these three nanofluids: SiO\textsubscript{2}/water, Al\textsubscript{2}O\textsubscript{3}/water or Fe\textsubscript{2}O\textsubscript{3}/water. The aforementioned metal oxides nanoparticles were dispersed in deionized water with different concentrations of 0.005, 0.01, 0.1, 1 and 5 wt. \%. These experimentations were also repeated four times at a fixed mass fraction of each metal oxide nanoparticle, and the error bars express the standard deviation obtained from the measurements. According to the obtained results, the average molar flux of SO\textsubscript{2} enhances about 28\% with the Al\textsubscript{2}O\textsubscript{3} nanoparticles enhancement from 0.005 to 0.1 wt. \%, and for higher nanoparticles loads, a substantial decrease resulted in its molar flux. In addition, the value of SO\textsubscript{2} absorption rate into SiO\textsubscript{2}/water nanofluid increases about 32\% when the mass fraction of SiO\textsubscript{2} nanoparticles in deionized water increases from 0.005 to 1 wt. \%. After a further increase of mass fraction up to 5 wt. \%, the absorption of CO\textsubscript{2} declines. Moreover, the value of CO\textsubscript{2} molar flux increases about 26\% when mass fraction of Fe\textsubscript{2}O\textsubscript{3} nanoparticles increases from 0.005 to 0.1 wt. \%; and with a further increase of nanoparticles mass fraction from 0.1 to 5 wt. \%, the value of CO\textsubscript{2} absorption declines. According to the results presented in Table 2, the maximum molar flux of SO\textsubscript{2} can be obtained with the nanoparticles mass fractions of 0.1, 1 and 0.1 wt. \% for Al\textsubscript{2}O\textsubscript{3}/water, SiO\textsubscript{2}/water and Fe\textsubscript{2}O\textsubscript{3}/water nanofluids, respectively. Similar to the results achieved for CO\textsubscript{2} absorption, the addition of nanoparticles into the deionized water enhances the micro-convections and intensifies the mass transfer rate of SO\textsubscript{2} while increasing the nanoparticles load increases further the viscosity of nanofluids, declining the absorption rate of SO\textsubscript{2} into the nanofluids [4,12]. The results presented in this figure show that SO\textsubscript{2} absorption in metal oxides nanofluids is more than that in deionized water.

These findings indicated that type of the used nanoparticles had a major effect on mass transfer rate. Moreover, these results indicate that the minimum value of CO$_2$ absorption, show that the absorption rate increases with the growth in volume loading rate, and when SiO$_2$/water is used as an absorbent, the maximum value of absorption rate is obtained at each gas volume loading rate; while for CO$_2$ absorption by using Fe$_2$O$_3$/water nanofluid, a higher absorption rate achieved. In addition, it is chiefly clear when Fe$_2$O$_3$/water is used as an absorbent, the maximum value of absorption rate is obtained at any volume loading rate. Moreover, these results indicate that the minimum value of CO$_2$ absorption for the Al$_2$O$_3$/water nanofluid resulted in comparison to the other nanofluids assessed in this work. These findings indicated that type of the used nanoparticles had a major effect on mass transfer rate. In addition, it can be concluded from this figure that the mass transfer flux is low at lower volume loading rates, and it increases with the increment of loading rate due to having a higher driving force of mass transfer.

Figure 8 also shows the results of average SO$_2$ absorption in each of these three nanofluids: SiO$_2$/water, Al$_2$O$_3$/water or Fe$_2$O$_3$/water against the volume loading rate that was measured at the temperature of 25 °C and the concentrations of 0.1, 1 and 0.1 wt. % for SiO$_2$, Al$_2$O$_3$ and Fe$_2$O$_3$ nanoparticles in deionized water, respectively. These findings reveal that the absorption rate increases with the enhancement in volume loading rate. Additionally, it is chiefly clear when Fe$_2$O$_3$/water is used as an absorbent, the maximum value of absorption rate is obtained at any volume loading rate. Moreover, these results indicate that the minimum value of CO$_2$ absorption for the Al$_2$O$_3$/water nanofluid resulted in comparison to the other nanofluids assessed in this work.

These results, which are similar to those obtained for CO$_2$ absorption, show that the absorption rate increases with the growth in volume loading rate, and when SiO$_2$/water is used as an absorbent, the maximum value of absorption rate is obtained at each gas volume loading rate; while for CO$_2$ absorption by using Fe$_2$O$_3$/water nanofluid, a higher absorption rate achieved. In addition, it is chiefly evident that the minimum value of SO$_2$ absorption for the Al$_2$O$_3$/water nanofluid resulted in comparison to the other nanofluids assessed in this work, that is similar to CO$_2$ case. These findings declared that type of the used nanoparticles and their interactions with CO$_2$ and SO$_2$ had a major effect on mass transfer rate of the gas into the nanofluids. Moreover, the value of absorption rate is similar to the case of CO$_2$ absorption.

Figure 6. Average molar flux of SO$_2$ versus mass fraction of metal oxides nanoparticles.

3.2.2. Probing of Mass Transfer Rate

Volume loading rate (mL/mL s), can be attributed to the rate of gas injection divided to the total volume of gas equal to which is 50 mL. It actually represents the time which is passing during the mass transfer process and clearly shows what portion of gas is injected through the nanofluid. Therefore, this parameter can easily show the ability of nanofluid to absorb gas at the beginning of the injection or at the end of the process. Figure 7 presents the results of average CO$_2$ absorption in each of these three nanofluids: SiO$_2$/water, Al$_2$O$_3$/water or Fe$_2$O$_3$/water against the volume loading rate that was measured at the temperature of 25 °C and the optimum mass fractions of 0.1, 0.01 and 1 wt. % for SiO$_2$, Al$_2$O$_3$ and Fe$_2$O$_3$ nanoparticles in deionized water, respectively. These findings reveal that the absorption rate increases with the enhancement in volume loading rate. Additionally, it is chiefly clear when Fe$_2$O$_3$/water is used as an absorbent, the maximum value of absorption rate is obtained at any volume loading rate. Moreover, these results indicate that the minimum value of CO$_2$ absorption for the Al$_2$O$_3$/water nanofluid resulted in comparison to the other nanofluids assessed in this work. These findings indicated that type of the used nanoparticles had a major effect on mass transfer rate. In addition, it can be concluded from this figure that the mass transfer flux is low at lower volume loading rates, and it increases with the increment of loading rate due to having a higher driving force of mass transfer.

Figure 8 also shows the results of average SO$_2$ absorption in each of these three nanofluids: SiO$_2$/water, Al$_2$O$_3$/water or Fe$_2$O$_3$/water against the volume loading rate that was measured at the temperature of 25 °C and the concentrations of 0.1, 1 and 0.1 wt. % for Al$_2$O$_3$, SiO$_2$ and Fe$_2$O$_3$ nanoparticles in deionized water, respectively. These results, which are similar to those obtained for CO$_2$ absorption, show that the absorption rate increases with the growth in volume loading rate, and when SiO$_2$/water is used as an absorbent, the maximum value of absorption rate is obtained at each gas volume loading rate; while for CO$_2$ absorption by using Fe$_2$O$_3$/water nanofluid, a higher absorption rate achieved. In addition, it is chiefly evident that the minimum value of SO$_2$ absorption for the Al$_2$O$_3$/water nanofluid resulted in comparison to the other nanofluids assessed in this work, that is similar to CO$_2$ case. These findings declared that type of the used nanoparticles and their interactions with CO$_2$ and SO$_2$ had a major effect on mass transfer rate of the gas into the nanofluids. Moreover, the value of absorption rate is similar to the case of CO$_2$ absorption.
absorption rate achieved. In addition, it is chiefly evident that the minimum value of SO\textsubscript{2} absorption for the Al\textsubscript{2}O\textsubscript{3}/water nanofluid resulted in comparison to the other nanofluids assessed in this work, that is similar to CO\textsubscript{2} case. These findings declared that type of the used nanoparticles and their interactions with CO\textsubscript{2} and SO\textsubscript{2} had a major effect on mass transfer rate of the gas into the nanofluids. Moreover, the value of absorption rate is similar to the case of CO\textsubscript{2} absorption.

**Figure 7.** Average molar flux of CO\textsubscript{2} versus volume loading rate.

**Figure 8.** Average molar flux of SO\textsubscript{2} versus volume loading rate.

### 3.2.3. Mass Transfer Coefficient

For the calculation of mass transfer coefficient, in separate runs, various volumes of gases (20, 25, 30, 35, 40, 45 and 50 mL that are, respectively, equal to 7, 10, 12, 13, 15.6, 17.6 and 20 min total gas-liquid contact time) were injected into the column and then gas concentration and molar flux were measured. Figure 9 shows the average molar flux of CO\textsubscript{2}/SO\textsubscript{2} against the dissolved concentration of CO\textsubscript{2}/SO\textsubscript{2} in the liquid bulk. These results clearly exhibit that an increase in CO\textsubscript{2}/SO\textsubscript{2} bulk concentration consecutively decreases the average value of molar flux due to the reduction of mass transfer driving force. Moreover this observation has approximately a linear behavior for all cases. In order to potpourri of this linear behavior, the principal mass transfer equation (Equation (7)) was used, and the experimental values for the absorption of CO\textsubscript{2}/SO\textsubscript{2} by using different nanofluids were fitted to Equation (7):

$$N_{Avg} = k_L (C_{\text{RO}_2,\text{Observed}} - C_{\text{RO}_2})$$  \hspace{1cm} (7)

where $k_L$ is the mass transfer coefficient at liquid phase, (m/s), $C_{\text{RO}_2}$ is the bulk concentration of CO\textsubscript{2}/SO\textsubscript{2} within the nanofluids, and $C_{\text{RO}_2,\text{Observed}}$ is the observed concentration of CO\textsubscript{2}/SO\textsubscript{2} at gas-liquid interface, (mol/m$^3$). It is mentioned that observed value for gas concentration in the interface was calculated
from extrapolation of line fitted on experimental data. Since linear pattern was assumed for molar flux and gas concentration. According to the results obtained for the absorption of CO$_2$ into each of these three nanofluids: SiO$_2$/water, Al$_2$O$_3$/water or Fe$_2$O$_3$/water (Figure 9a–c), the model was fitted to the experimental data with the R$^2$ equal to 0.9753, 0.9755 and 0.9897 declaring high accuracy of the regression analysis and low deviation of the experimental data from the fitted model.

![Graphs showing molar flux versus CO$_2$ bulk concentration](image)

**Figure 9.** Average molar flux versus CO$_2$ bulk concentration for (a) SiO$_2$/water, (b) Al$_2$O$_3$/water and (c) Fe$_2$O$_3$/water nanofluids.
The average molar flux of $\text{SO}_2$ versus the bulk concentration is shown in Figure 10. These results are also similar to those obtained for $\text{CO}_2$ absorption declaring that an increase in $\text{SO}_2$ bulk concentration leads to decrease the average value of molar flux, representing a significant declination in mass transfer driving force. In order to obtain the mass transfer coefficient and $\text{SO}_2$ concentration at the bubbles-liquid interface, the regression analysis was also performed on Equation (7), and the equation was fitted to the values for $\text{SO}_2$ absorption into each of these three nanofluids: $\text{SiO}_2$/water, $\text{Al}_2\text{O}_3$/water or $\text{Fe}_2\text{O}_3$/water (Figure 10a–c) with the $R^2$ equal to 0.9711, 0.9705 and 0.9788, respectively. These values confirm the high accuracy of the regression analysis.

According to the results obtained from Figures 9 and 10, it can be concluded that for all nanofluids used in this study, the vertical diagram (dashed line) shows the observed concentration of $\text{CO}_2$ and $\text{SO}_2$ at the bubble-liquid interface. Furthermore, the diagonal plot of average molar flux versus the bulk concentration of $\text{CO}_2$ and $\text{SO}_2$ represents the operating line for gas absorption into the nanofluids. It is clearly evident that by approaching the operating line to the equilibrium concentration of $\text{CO}_2$ and $\text{SO}_2$ in each of these three nanofluids, namely $\text{SiO}_2$/water, $\text{Al}_2\text{O}_3$/water or $\text{Fe}_2\text{O}_3$/water, a lower molar flux resulted.
Table 3 represents the values of relative mass transfer coefficient for SO$_2$ and CO$_2$ absorption using SiO$_2$/water, Al$_2$O$_3$/water or Fe$_2$O$_3$/water nanofluids with respect to water alone. These values are the slope of operating line in Figures 9 and 10. According to these results, the maximum value of relative mass transfer coefficient for CO$_2$ absorption was achieved by Al$_2$O$_3$/water nanofluid while the value of relative mass transfer coefficient for SiO$_2$/water was observed to possess a minimum value in comparison to the other nanofluids assessed in this work. Additionally, these findings exhibit that the maximum value of mass transfer coefficient for SO$_2$ absorption was achieved for SiO$_2$/water, and this parameter for Fe$_2$O$_3$/water was found to be less than the others. According to the results presented in this table, relative mass transfer coefficient intensively depend on type of the nanofluid. In fact, the absorption of SO$_2$ by SiO$_2$/water nanofluid and the absorption of CO$_2$ by Al$_2$O$_3$/water nanofluid demonstrate higher values for the relative mass transfer coefficient and relative gas concentration at the bubble-liquid interface.

### 3.3. Diffusivity Coefficient

In general, diffusivity of gases into a fluid has a higher impact on mass transfer coefficient as well as rate of gas absorption. In this study, Equation (8) was used to obtain the diffusivity of SO$_2$ and CO$_2$ into each of these three nanofluids, namely SiO$_2$/water, Al$_2$O$_3$/water or Fe$_2$O$_3$/water. This equation...
indicates a bubble-liquid mass transfer model for raising a single bubble through a liquid based on Dankwert’s theory \[5,29\].

\[
N_{Av} = \frac{D \sinh(\sqrt{s/D}) + D r_0 \sqrt{s/D} \cosh(\sqrt{s/D})}{r_0 \sinh(\sqrt{s/D})} (C_{RO_2,i} - C_{RO_2})
\]  \(8\)

In this model, the main factors affecting on mass transfer rate are the surface renewal rate \(s\), bubbles radius \(r_0\), diffusion layer thickness \(\delta\) and the diffusivity of gases through a liquid \(D\). \(N_{Av}\) is the molar flux \((mol/m^2 s)\), \(C_{RO_2}\) and \(C_{RO_2,i}\) are the concentration of dioxide gases within the liquid bulk and at the bubble-liquid interface \((mol/m^3)\), respectively.

By comparing Equations (7) and (8), the mass transfer coefficient of a gas into the liquid by using a single bubble can be obtained from the following relation:

\[
k_L = \frac{D \sinh(\sqrt{s/D}) + D r_0 \sqrt{s/D} \cosh(\sqrt{s/D})}{r_0 \sinh(\sqrt{s/D})}
\]  \(9\)

This equation was used for estimating the diffusivity of \(SO_2\) and \(CO_2\) within the nanofluids. It has been reported by Darvanojoghi et al. that the effective parameters in Equation (9) \(s, \delta\) and \(D\) intensively depend on the size of nanoparticles in the basefluid. They reported that the size of nanoparticles was about 40 to 50 nm, and the values of surface renewal rate, \(s\), and the diffusion layer thickness, \(\delta\), were 6.85 and 0.201 mm, respectively \[2\]. In this research, the average mean diameter of nanoparticles ranges from 40 to 60 nm. Additionally, it can be assumed that the values of \(s\) and \(\delta\) would be constant during the absorption of \(SO_2\) and \(CO_2\) and depend on just nanoparticles mean diameter. Additionally, the mass transfer coefficients for both \(SO_2\) and \(CO_2\) gases within the nanofluids studied here have been already calculated in Table 3. Therefore, Equation (9) can be simplified to the following relation:

\[
F(D, s, \delta) = \exp\left(2\delta \sqrt{\frac{s}{D}}\right) + \frac{D - r_0 \sqrt{s/D} - r_0 k_L}{r_0 \sqrt{s/D} - r_0 k_L} = 0, \ s = 6.85 \ and \ \delta = 0.201
\]  \(10\)

where \(F(D, s, \delta)\) must be equal to zero for certain values of mass transfer coefficient and gas diffusivity within the different nanofluids. By using the Newton-Raphson method, Equation 10 can be solved according to the following equation in which \(\partial F(D_n, s, \delta)/\partial D_n\) can be obtained by obtaining partial derivative of Equation (10). The initial value of diffusivity, \(D_0\), was set on \(10^{-10}\).

\[
D_{n+1} = D_n - \frac{F(D_n, s, \delta)}{\partial F(D_n, s, \delta)/\partial D_n}, \ n = 0, 1, 2, 3, \ldots
\]  \(11\)

Table 4 presents the values of \(SO_2\) and \(CO_2\) diffusivities into \(SiO_2/water\), \(Al_2O_3/water\) or \(Fe_2O_3/water\) nanofluids. According to the results obtained from Table 4, it is evident that the maximum value of diffusivity for the absorption of \(CO_2\) is obtained when water/\(Fe_2O_3\) is used as an absorbent, and the maximum diffusivity for the absorption of \(SO_2\) is achieved when being used water/\(SiO_2\) nanofluid. As can be seen in this table, for nanoparticles with the higher density \(\rho_{SiO_2} = 2.196 \ g/cm^3, \rho_{Al_2O_3} = 3.980 \ g/cm^3, \rho_{Fe_2O_3} = 5.242 \ g/cm^3\) more diffusivity of \(CO_2\) within the nanofluid is observed which is attributed to the nanoparticles Brownian motion inducing more diffusion of \(CO_2\) molecules at the bubble-liquid interface. It has been previously reported by Attari et al. that the momentum caused by Brownian velocity of nanoparticles leading to produce micro-convections, depending on nanoparticles density according to the following relation \[20\]:

\[
Mo_{Brownian} = \lambda \sqrt{p_T}
\]  \(12\)

According to this equation by having an increase in nanoparticles density, more momentum can be transferred through the liquid phase; and consequently, a higher magnitude of micro-convections produces. Previous efforts declared that only two significant mechanisms including Brownian micro-convections and grazing effect (absorption of gas molecules by nanoparticles at the bubble-liquid interface and desorption of them into the liquid) can be involved during the gas absorption when a nanofluid is used as an absorbent [2–5,10,11,36]. For the absorption of CO$_2$, Brownian mechanism has a major impact on gas molecules transfer due to the fact that CO$_2$ molecules have not a very polar structure and asymmetric molecular configuration to produce high molecular charges (O=C=O) for being absorbed by nanoparticles surface charge; therefore, the Brownian mechanism indicates that the SiO$_2$ nanoparticles are the most suitable absorbent due to their high surface density and high magnitude of micro-convections produced. Consequently, the minimum value of CO$_2$ diffusivity in water/SiO$_2$ nanofluid could be observed due to the lower density and lower magnitude of micro-convections produced by SiO$_2$ nanoparticles.

On the other hands, due to the high polarity of SO$_2$ molecules and formation of its Lewis structure during the absorption process [37] (Figure 11), it can be easily absorbed by means of nanoparticles surficial charge, which they are at the vicinity of the bubble-liquid interface. In addition, it is reported from the previous researches that SiO$_2$ nanoparticles have a high value of surface charge due to the formation of silanol bonds (Si-O-H) at the nanoparticles surface [12], which has been confirmed by Zeta Potential test presented in this study. Therefore, the main mechanism for the absorption of SO$_2$ is attributed to grazing effect by means of nanoparticles at the bubble-liquid interface resulting a high diffusivity of SO$_2$ gas when water/SiO$_2$ nanofluid is used (Figure 11).

![Figure 11. Schematic diagram of grazing effect of SiO$_2$ nanoparticles during the absorption of SO$_2$.](image)

**3.4. Correlation**

Froessling [38] estimated the mass transfer of a raising bubble in a liquid by using Equation (13):

\[
Sh = 0.6(Re)^{1/2}(Sc)^{1/3}
\]  

(13)
Equation (13) was found to be a suitable correlation for prediction of the absorption of different gases into wide ranges of liquids by means of single bubble absorber system [39]. In order to estimate $Sh$ number for the gas absorption by nanofluids, other physical properties including dynamic viscosity, kinematic viscosity, and density of nanofluids were needed to obtain according to the following relations [40]:

\[
\mu_{nf} = \mu_{bf}(1 - \phi)^{2.5}  \tag{14}
\]

\[
\rho_{nf} = \phi \rho_p + (1 - \phi) \rho_{bf}  \tag{15}
\]

\[
\nu_{nf} = \mu_{nf} / \rho_{nf}  \tag{16}
\]

where $\phi$ is the volume fraction of oxides nanoparticles within the deionized water (can be obtained by using Equation (17) $\mu_{bf}$ is the dynamic viscosity of the deionized water, $\rho_p$ is the bulk density of nanoparticles (presented in Table 1) and $\rho_{bf}$ is the density of the deionized water (1000 kg/m$^3$).

$$q(\%vol) = \frac{w(\%wt)}{w(\%wt) + \frac{\rho_p}{\rho_{nf}}(100 - w(\%wt))}$$  \tag{17}

The values of $Re$, $Sc$ and $Sh$ can be calculated using the following equations:

\[
Re_b = U_b d_b / \nu_{nf}  \tag{18}
\]

\[
Sc_{nf} = \nu_{nf} / D_{nf}  \tag{19}
\]

\[
Sh_{nf} = k_{nf} d_b / D_{nf}  \tag{20}
\]

In these equations, $U_b$ means the bubble rising velocity in the column that was approximately found to be 0.21 m/s for all the experiments. Additionally, $d_b$ is the bubble diameter that was measured as 7 mm for all cases. Table 4 also presents the values of $Re_b$, $Sh$ and $Sc$ for the absorption of CO$_2$ and SO$_2$ by using the mentioned nanofluids.

According to Table 4 and Equation (18), the value of Reynolds number does not change significantly when either nanofluid or pure basefluid is applied during the absorption process by means of raising a single bubble absorber i.e., $\nu_{nf} \approx \nu_{bf}$. Therefore, it can be assumed that the Reynolds number has no significant effect on relative Sherwood number and this parameter is found to be just as a function of relative Schmidt number according to below:

\[
\frac{Sh_{nf}}{Sh_{bf}} = K \left( \frac{Sc_{nf}}{Sc_{bf}} \right)^m  \tag{21}
\]

$m$ and $K$ were calculated by using a two-dimensional regression analysis over the experimental data shown in Figure 12. According to this figure, the following equation was obtained for the mentioned parameters with the $R^2 = 0.9919$. Equation (22) can predict the Sherwood number for various gas-nanofluid absorption systems at $Re_b \sim 1300$, accurately:

\[
\frac{Sh_{nf}}{Sh_{bf}} = 1.3643 \left( \frac{Sc_{nf}}{Sc_{bf}} \right)^{0.6125}  \text{ for } Re_b \approx 1300  \tag{22}
\]

It is mentioned that $Sh_{bf}$ can be calculated by the Froessling equation (Equation (13)).

4. Conclusions

In this research, the absorption of SO$_2$ and CO$_2$ was elucidated by using a single-bubble column absorption setup into water based nanofluids containing SiO$_2$, Fe$_2$O$_3$ or Al$_2$O$_3$ nanoparticles. The results of this study clearly show that the aforementioned nanofluids have high stability since the zeta potential is lower than $-45$ mV. The results of TEM and DLS analysis also display that the average size of nanoparticles is within limit of 40–60 nm.

These results also declared that the maximum absorption of CO$_2$ and SO$_2$ could be obtained when water/SiO$_2$ or water/Fe$_2$O$_3$ nanofluid is utilized as an absorbent. Moreover, our findings also showed that the maximum relative absorption for SO$_2$ and CO$_2$ in the studied nanofluids in comparison to base fluid occurs when a water/Fe$_2$O$_3$ or water/SiO$_2$ nanofluid was used as the absorbent. Indeed, our results show that the type of gas molecules and nanoparticles determines the mechanism of mass transfer intensification of nanofluids. Therefore, both Brownian motion and grazing effect play crucial role for the increment of mass transfer in gas absorption by nanofluids. According to the type of gas and nanoparticles, the major mechanism can be distinguished.

In addition, mass transfer parameters incorporating diffusivity of gases into the oxides nanoparticles loaded in nanofluids, Sherwood number and Schmidt number were obtained. The results exhibit that the addition of nanoparticles (due to increment of Brownian momentum) increases diffusivity coefficient, and the maximum diffusivity for CO$_2$ and SO$_2$ absorption was obtained for water/Fe$_2$O$_3$ and water/SiO$_2$ nanofluids, respectively.

Finally, a new correlation is offered for the prediction of Sherwood number versus Schmidt number in gas-nanofluid systems (for Re$_b$ about 1300) in which the experimental values are predicted with high accuracy.

Nomenclature

- **N**: Molar flux (mol/m² s)
- **C**: Gas concentration at liquid bulk (mol/m³)
- **C_{\text{obs}}**: The observed gas concentration at gas-liquid interface (mol/m³)
- **V**: Volume of nanofluid in the single bubble absorber (m³)
- **n**: Number of bubbles
- **r_0**: Average radius of bubbles (m)
- **k_L**: Mass transfer coefficient in liquid phase (m/s)
- **D**: Diffusion coefficient (m²/s)
- **δ**: Diffusion layer thickness (mm)
- **s**: Renewal surface factor (1/s)
- **Re_b**: Reynolds number (U_b d_b / ν_{nf})
- **Sc**: Schmidt number (ν_{nf} / D_{nf})
- **Sh**: Sherwood number (k_L d_b / D_{nf})
- **d_b**: Diameter of bubbles raising through nanofluid (m)
- **ϕ**: Volume fraction (%)
- **w**: Mass fraction (%)
- **ρ**: Density (kg/m³)
- **v**: Kinematic viscosity (m²/s)
- **λ**: Constant value for calculation of Brownian momentum transfer
- **R_{\text{eff}}**: Relative absorption rate (N_{nf} / N_{bf})
- **M**: HCl molarity (mol/lit)
- **λ**: Constant value as a function of nanoparticles density, temperature, volume fraction, mean diameter, heat capacity, and Boltzmann constant.
- **Mo**: Momentum that can be transferred by means of nanoparticle random motion

Subscript

- **nf**: Nanofluid
- **bf**: Basefluid
- **p**: Nanoparticles
- **B**: Bubble
