Abstract: Recently, the API X100 steel has emerged as an important pipeline material for transportation of crude oil and natural gas. At the same time, the presence of significant amounts of hydrogen sulfide (H\textsubscript{2}S) in natural gas and crude oil cause pipeline materials to corrode, which affects their integrity. In this study, the effect of H\textsubscript{2}S concentration on the corrosion behavior of API X100 in 3.5\% NaCl solution is presented. The H\textsubscript{2}S gas was bubbled into saline solutions for different durations, and the corrosion tests were then performed using potentiodynamic polarization and electrochemical impedance spectroscopy (EIS). X-ray photoelectron spectroscopy (XPS), X-ray diffraction (XRD), atomic force microscopy (AFM), and scanning electron microscopy (SEM) techniques were used to characterize the corroded surface. The results indicate that the corrosion rate of API X100 steel decreases with increasing H\textsubscript{2}S bubbling time due to the increase in H\textsubscript{2}S concentration in 3.5\% NaCl solutions. It is noticed that an accumulation of a critical amount of hydrogen in the metal can result in hydrogen-induced crack initiation and propagation. It was further observed that, when the stress limit of a crystalline layer is exceeded, micro-cracking of the formed protective sulfide layer (mackinawite) occurs on the API X100 steel surface, which may affect the reliability of the pipeline system.

Keywords: H\textsubscript{2}S concentration; corrosion; sour environment; API X100 steel; sulfide layer

1. Introduction

Pipelines are one of the most convenient means of transporting petroleum and its products from one region to another. Carbon steels (C-steel) are commonly used as a material for the transportation pipelines because of their economic advantages and their ability to withstand operating pressure [1,2]. However, the steel surfaces of pipelines are constantly exposed to corrosive environments during the transportation of the petroleum and its products; hence, the integrity of the pipeline system is always found to be affected [3–5]. The sulfur content in the petroleum and its products have been shown to be instrumental in the internal corrosion of C-steel pipelines [6]. Sulfide is predominant in aqueous solutions through industrial waste and various biological processes and has a significant influence on the aqueous corrosion of steels [7]. Other parameters such as temperature, fluid, velocity, and microstructure also are influential in the corrosion rate of C-steel used in the petroleum industry [5,8–11].

Recently, attentions have been drawn to the sour corrosion of C-steel due to a poor understanding of sulfide corrosion absorption. Many researchers have shown that the formed iron sulfide on the steel surface during the sour corrosion process can be either protective or non-protective [12,13]. It has
been reported that the formed corrosion product layer during the corrosion of API X52 is significantly composed of iron sulfide and various oxides, which enhance the protective properties of the film [4]. In a similar study, the corrosion of API X52 steel in H$_2$S revealed that the increase in the thickness of formed iron sulfide film influences the corrosion rate of C-steel [14]. It has also been reported that, when the stress limit of the formed sulfide layer exceeds, micro-cracks within the formed layers have formed, allowing a more rapid penetration of sulfide and chloride species into the deposit, resulting in an increase in the corrosion rate [15].

The properties and the composition of the steel play critical roles in the formation, nature and stability of the sulfide layer and consequently its corrosion prevention behavior [3]. A recent study [16] has shown that the chemical composition and microstructure of C-steel significantly influence its resistance to corrosion in wet H$_2$S environments. However, the needs to increase the strength and reduce the corrosion rate of existing C-steel pipeline materials have inspired new interest in the quest for higher-strength steels [17,18]. Despite several contributions of different authors regarding a shared understanding of the corrosion of steel materials [19,20], few studies have investigated the corrosion in a sour environment [21,22], especially at low temperatures and with higher grades of carbon steel. The application of this high strength steel as a pipeline material is aimed at enhancing the corrosion resistance of pipeline steel. Nevertheless, many of the electrochemical characteristics of these high strength low-alloy steel materials have not yet been reported in the literature [23–27]. Furthermore, the corrosion behavior and mechanism of these steels in sulfide environments have not yet been fully understood. Here, the corrosion behavior and mechanism of API X100 steel in sour 3.5% NaCl solution at different H$_2$S concentrations are presented using experimental tools, while surface characterization techniques are used to characterize the corroded surface.

2. Materials and Methods

2.1. Material Preparation

The pipeline steel plates supplied by Hebei Yineng Pipeline Group Co., Ltd. (Shandong, China) were cast into slabs after ladle refining and hot-rolled into 10 mm thickness plates. This process was followed by solid-solution fine-grain strengthening, precipitation, and controlled cooling to achieve the desirable microstructure. The microstructure of the as-received samples were found to be pearlitic, formed by cooling the austenite. A representative microstructure of the target steel is shown in Figure 1.

![Figure 1. Scanning electron microscopy (SEM) micrograph of API X100 steel.](image)

The chemical composition of the API X100 steel used in the present study was determined by an optical emission (OE) spectrometer, ARL 3460 (Thermo Fisher Scientific SARL, Ecublens,
Switzerland). The sample preparation procedure and the chemical composition are detailed elsewhere [28,29].

2.2. Electrochemical Measurement Setup

Different electrochemical experiments were carried out at various H$_2$S concentrations using an experimental setup that was described elsewhere [28]. Figure 2 shows the schematic diagram of the corrosion set-up used in this study.

![Figure 2. Schematic diagram of the corrosion test set-up employed to study the corrosion behavior of API X100 steel at room temperature.](image)

The set-up was designed to allow and control the bubbling of both H$_2$S and N$_2$ into the saline electrolyte solution. In the experimental study, the work was designed to investigate the corrosion behavior of API X100 steel material in 3.5% NaCl solutions bubbled with H$_2$S gas at different durations. De-aeration was carried out using nitrogen gas for 2 h prior to bubbling H$_2$S gas into the saline solutions at a pressure of 0.5 MPa and regulated using a flow meter (CVG Technocrafts, Mumbai, India) for different time intervals before each test. In addition, both the pH and the H$_2$S concentration of the solution were measured and calculated, respectively, at the end of each test (Table 1). The actual concentration of H$_2$S in the solution was determined following the NACE standard [30], as shown in Table 1.

For reproducibility, each test was repeated three times. The electrochemical impedance spectrometer (EIS) experiments were conducted within a frequency range of 0.1 to 100 KHz starting from the higher limit towards the lower one. The potentiodynamic polarization experiments were done using a Gamry Reference Eco potentiostat (Gamry Instruments, Warminster, PA, USA) at...
a scan rate of 0.167 m·Vs⁻¹. The purity of the used gas, H₂S, was 99.99% and was purchased from Buzwair Scientific & Technical Gases, Doha, Qatar. The 3.5% NaCl solution was prepared using deionized water with a conductivity of 18.6 µSiemens. A JEOL JSM-7800F scanning electron microscope (SEM, Peabody, MA, USA) and atomic force microscopy (AFM) (JPK Instruments, Berlin, Germany) were used to capture micrographs to document and compare the surfaces before and after the corrosion. Energy dispersion X-ray (EDX) (AZoNano, Manchester, UK) and Kratos Axis Ultra DLD X-ray photoelectron spectroscopy (XPS) units (Kratos Analytical Ltd, Manchester, UK) were used to qualitatively and quantitatively measure the elemental composition of the formed corrosion product layers at different H₂S concentrations.

3. Results and Discussion

3.1. Potentiodynamic Polarization

Figure 3 presents the typical potentiodynamic polarization curve of API X100 steels in 3.5% NaCl solution and at different H₂S concentrations.

![Figure 3. Potentiodynamic polarization curves of API X100 steels.](image)

The corrosion current decreases as the anodic current and the potential were scanned from open circuit potential (OCP) in the anodic direction at different H₂S bubbling durations, which confirms that the protective nature of the formed sulfide film increases due to the increase in bubbling duration. The decrease in the cathodic current with increasing bubbling duration is attributed to two opposing factors: the pH and the H₂S gas concentrations in the solution [10]. Table 2 shows the Tafel parameters derived from the Tafel measurements shown in Figure 3.

3.2. Electrochemical Impedance Spectroscopy (EIS)

The resistance of carbon steel materials to corrosion depends significantly on the physicochemical properties of the material [31]. Figure 4 shows the measured electrochemical impedance spectra
(Nyquist and Bode formats) within a frequency range of 0.1 to 100 KHz starting from the highest to the lowest frequency limit. The corresponding fitted data (dotted line) are also within a frequency range of 0.1 to 100 KHz in 3.5% NaCl solutions saturated with H$_2$S gas at 0, 7, 14, and 21 ppm concentrations. All values were obtained using the Gamry Echem Analysis Software technique [32].

Nyquist and Bode with the phase angle plots obtained for API X100 steel materials tested in 3.5% NaCl solution with and without H$_2$S are shown in Figure 4. An increase in resistance with increasing H$_2$S concentration can be seen in the impedance behavior of the API X100 steel. The Nyquist plot of the API X100 steel without H$_2$S displays a defined single smaller semicircular shape, while the tests with H$_2$S showed increasing semicircular curves (Figure 4). The fitting was done using the equivalent circuit shown in Figure 5. The values of the fitted data are shown in Table 3. In the diagram, $R_s$ represents the solution resistance; CPE in the circuit is the constant phase element; $W$ is the mass transfer Warburg element [33]. $R_{ct}$ stands for the charge transfer resistance, and $R_{po}$ is the pore resistance.

It can be observed that an increase in hydrogen sulfide concentration increased the charge transfer resistance ($R_{ct}$) of the steel [34].
The increase in $R_{ct}$ indicates that the sulfide film is becoming more protective. Additionally, the higher the $R_{ct}$ is, the lower the double layer capacitance will be. As can be seen in Table 3, the most protective sulfide layer was at a hydrogen sulfide concentration of 21 ppm. The corrosion resistance of the API X100 steel increases when the hydrogen sulfide concentration is increased from 0 to 21 ppm. This observation is attributed to the iron sulfide film formation and growth [13,35], which is in good agreement with the findings of Tang et al. [36], who observed similar iron sulfide film deposits on the SAE-1020 carbon steel when exposed to a sour environment. Furthermore, the increase in the hydrogen sulfide concentrations from 14 to 21 ppm showed evidence of crack development, which may be ascribed to hydrogen-induced cracking (HIC). The hydrogen-induced crack (HIC) has been reported to be one of the most significant damage modes in a sour environment [37,38]. It is believed that hydrogen atoms produced due to surface corrosion of the steel diffuse into it through microstructural defects that exist in the material [38]. The accumulation of a critical amount of hydrogen in the metal defeats results in HIC initiation and propagation, as recently reported by Kittel et al. [39].

It is demonstrated that the corrosion resistance of API X100 steel material enhances significantly with increasing sulfide concentration, and can be attributed to the formation of a protective iron sulfide layer on the API X100 steel surface when exposed to an aqueous hydrogen sulfide environment. A previous study [40] has shown that a chemical reaction occurs in a sour environment when $\text{H}_2\text{S}$ is bubbled into the aqueous solution. However, some authors have reported the occurrence of supersaturated mackinawite when low concentrations of $\text{H}_2\text{S}$ are combined with an increase in $\text{Fe}^{2+}$ concentration, resulting in the growth of mackinawite on the steel surface [41–44]. Furthermore, several authors [45,46] have also reported the significant effects of $\text{H}_2\text{S}$ concentration on the sulfide layer formation.

3.3. Surface Characterizations

The atomic force microscopy (AFM) technique was used for a better understanding of the corroded API X100 steel surface. The 3D AFM images of the corroded surfaces are presented in Figure 6a–d. It is evident that the surface roughness increases with increasing $\text{H}_2\text{S}$ concentration. The specimens corroded at highest $\text{H}_2\text{S}$ concentration have the highest surface roughness ($Ra = 400$ nm), while the specimens tested in the absence of $\text{H}_2\text{S}$ have the lowest surface roughness ($Ra = 50$ nm). This behavior can be ascribed to the increase in the formation of more scale layers on the API X100 steel surfaces with increasing concentration of $\text{H}_2\text{S}$ (Figure 6).

![Figure 6. 3D atomic force microscopy (AFM) images of API X100 steel exposed to a sour environment at different $\text{H}_2\text{S}$ concentrations of (a) 0 ppm; (b) 7 ppm; (c) 14 ppm; (d) 21 ppm.](image-url)
Evidence of the sulfide layer formation of sulfide layer on the surface of the API X100 steel specimen when tested in an H₂S environment was confirmed by EDX analysis. The presence of sulfur (S) peak in the EDX spectra shown in Figure 7b–d clearly confirms the formation of a sulphide layer on the surface of all API X100 steel tested under H₂S environment. However, there was no evidence of “S” in the spectra taken from the test specimen performed without H₂S (Figure 7a).

![Figure 7 SEM images of API X100 steel material for tests conducted in 3.5% NaCl (a) without H₂S, (b) with 7 ppm of H₂S, (c) with 14 ppm H₂S, and (d) with 21 ppm H₂S.](image-url)

Evidence of cracks can be seen on the sulfide layers at different H₂S concentrations, especially at higher concentrations (Figure 7). The phenomenon of the formation of a sulfide film and its cracking is
influenced by test solution conditions [47]. It is clear from Figure 7 that deposits of iron sulfide layers have been built up on the sample surface (Figure 7). SEM micrographs shown in Figure 7 reveal that the sulfide layers appear finer and more clustered as the H$_2$S concentration is increased, which can be attributed to the formation of a more homogeneous protective iron sulfide layer on the steel surface. It has been reported that the continuous diffusion of hydrogen sulfide on a steel surface can lead to generate internal stresses into the formed sulfide layer [15]. Upon exceeding the stress limit of the crystalline layer, micro-cracking of the formed layers occurs as observed in Figure 7b–d. Analysis of the corroded metal surface state can be carried out using surface X-ray photoelectron spectroscopy analysis techniques. Figure 8 displays the survey XPS spectra of API X100 steel after exposure to different H$_2$S concentrations. The presence of iron peaks at 709.82 eV, 713.53 eV and a carbon peak at 285.5 eV can be noticed. However, the peaks at 163 and 170 eV binding energy (Figure 8b) indicate the presence of sulfur and thus deduce the possible formation of sulfide layers on the corroded API X100 steel surfaces. This is in good agreement with previous studies [48].

Figure 9 shows the XRD spectra of the corroded API X100 steel samples in saline and sour solutions. XRD peaks located at different 2$\theta$ values confirm the presence of different iron compounds. The test performed in the absence of H$_2$S shows a diffraction pattern typical of the peak of iron oxide (Fe$_2$O$_3$, 2$\theta$ = 65.08°) [4]. However, the presence of iron sulphide also referred to as mackinawite (FeS, 2$\theta$ = 82.43°) was observed on the surface of API X100 steel surface when exposed to different H$_2$S concentrations.

![Figure 8. X-ray photoelectron spectroscopy (XPS) fitting spectra obtained from (a) the survey and (b) the sulfur spectra with a fitted line of corroded API X100 steel at 21 ppm of H$_2$S.](image-url)
Several researchers have reported that the initial formation of mackinawite layer on the steel surface before the formation of the more stable sulfide species depends on the sample material and the test conditions [49,50]. The presence of this iron sulphide (mackinawite) layer provides some protection to the surface of the material from further corrosion due to its structural orientation [51], resulting in a decrease in the corrosion rate. This protective iron sulfide layer becomes more homogeneous and dense with increasing H₂S concentration as can be observed in the SEM micrographs (Figure 7). Similar studies have shown that iron and sulfide films were observed on API X52 pipeline steel surface when exposed to sour environments [4]. However, their quantity is sensitive to the experimental procedure [4,52]. Subsequently, iron sulfide layer (mackinawite) is formed due to the presence of iron and sulfide ions in the solution. Nevertheless, an increase in the sulfide concentration as seen in this test decreases the iron concentration in the solution, resulting in the precipitation of protective iron sulfide on the steel surface [53].

4. Conclusions

In order to understand the effect of hydrogen sulfide on the corrosion behavior of API X100 steel, sets of experiments in the presence and absence of sulfide in 3.5% NaCl were performed on API X100 steel. Based on the experimental results, the following can be concluded:

1. EDX and XPS analyses confirm the presence of sulfur on the corroded API X100 steel surfaces at different H₂S concentrations.
2. A significant decrease in the corrosion rate of API X100 steel in 3.5% NaCl solutions containing various concentrations of H₂S is noticed which can be attributed to the formation of sulfide layer.
3. SEM micrographs confirm that the formed protective sulfide layer becomes more homogenous and denser as the H₂S concentration is increased.
4. The formation of more homogeneous, dense and protective iron sulfide layer (mackinawite) is responsible for the decrease in the corrosion rate with increasing concentration of H₂S.
