Abstract: The flow characteristics in the vicinity of a set of half-cylinders of different sizes simulating benthic objects were studied experimentally using particle image velocimetry (PIV). The cylinders were mounted on the bottom of an open channel, and the influence of the flow speed on the distribution of the shear stress along the bottom geometry was investigated. Of special interest was how the shear stress changes close to the wall as a function of the flow speed and cylinder arrangement. It was found that the shear stress varies significantly as a function of position. This implies habitat heterogeneity allowing benthic invertebrates with different shear stress tolerance exists when the bottom consists of differently sized stones. It was also shown that direct measurements of near wall velocity gradients are necessary to accurately calculate the wall shear stress for more complex geometries.

Keywords: shear stress; PIV; benthic fauna; river; stones

1. Introduction

The interaction between flowing water in rivers and the riverbed environment and ecology has been studied actively for a long time. Hynes (1972) [1] made a comprehensive review of the published material up to the actual year, showing the importance of an understanding of the near-bed flow dynamics. Since then, a number of studies have been presented, some with focus on the correlation between the distribution of macroinvertebrates and the local flow properties in terms of velocity, shear stress $\tau$, and turbulence. A majority of these studies consider the dependence of $\tau$ on the benthic fauna and the flow dynamics in general connected to riverbed objects.

Hydro power plants have direct implications on the river systems upon which hydropower plants are built. As hydropower electricity generators are started, varied in their power output or stopped, the river flow is disturbed, and the flow and, thus, the velocity and/or the water level change accordingly. Poff and Zimmerman (2009) [2] published a review covering the past forty years of relevant research supporting the notion that flow variations can lead to ecological changes, possibly in proportion to the degree of change. Changes in water levels may, for instance, imply stranding of species, including fish [3]. Further, flow pattern variations can cause large disturbances. Macro-invertebrates, for example, are especially susceptible to flow velocity fluctuations. The energy for invertebrates or fauna required to maintain a position within the turbulent bottom flow must be satisfied by adequate nutrition and oxygen that the fluctuating conditions bring [4] (M’erigoux and Dol’edec, 2004). The macro-invertebrates play a fundamental role in the food-chain by filtering and cleaning decaying
matter in the river, and they also constitute food-stock for larger animals, such as birds and fish. The overall vitality of macro-invertebrates depends on the magnitude and type of flow alteration. Hence, hydraulic conditions can have a profound effect on lotic species living in the vicinity of the bottom of the river, and it is therefore of large interest to understand how the flow changes close to river beds as the overall flow rate within a river change.

It must be noted that not all flow changes are necessarily detrimental to the ecosystem. Lotic species often adapt to prevailing flow conditions; and as a crude example, two species of caddis larvae: Hydropsyche instabilis and Plectrocnemia conspersa are found to thrive, respectively, on fast and slow-moving waters [5] (Allen, 2007). In some instances, changes in river velocity may lead to the relocation of one species but the flourishing of another.

Dol´edec et al. (2007) [6] investigated the preferences of benthic macroinvertebrates [7] in relation to $\tau$ using FließwasserStammTisch hemispheres, which is a field measuring technique to measure $\tau$ along river beds [8]. If flow disruptions are unavoidable, artificial structures such as current deflectors and overhanging shelves can be constructed to mitigate the effects that hydropower regulation has upon the flow characteristics. These features can serve as effective habitat protectors [9] (Jeffries and Mills, 1990). Both flow disturbance avoidance and mitigation initiatives require the knowledge of how the flow is disrupted by the changes.

In this experimental study, the objective related to the varying flow rates in regulated rivers by analysis of how the distribution of $\tau$ along model benthic objects depends on the flow rate. Of main interest is how a large proportion of the model benthic objects comprise a livable environment based on a value of $\tau$ being below a critical value, $\tau_c$. It is also of interest to compare alterations in averaged $\tau$ when changing the flow rate to temporal variations in $\tau$ due to fluctuations at a constant flow rate.

For the model experiments, an open water channel was used with acrylic half-cylinders placed on the channel bottom mimicking benthic objects (stones) and particle image velocimetry (PIV) was used to explore the flow. PIV is a non-intrusive technique providing whole-field measurements of the flow [10,11]. One advantage with the technique as compared to measurements limited to small control volumes like laser doppler velocimetry (LDV) [12] is that full picture snap-shots of the flow behavior are obtained in each measurement. The reason to do model experiments in a laboratory as in References [11,13] rather than in situ measurements is the, in general, complex PIV experimental set-ups in terms of seeding possibilities, camera, cumbersome and sensitive laser, and evaluation hardware. Hence, it is difficult to perform in situ PIV experiments with quality and trust. Still, it can be mentioned that a portable PIV system exists [14] (Trifico et al., 2007) and is a highly interesting method for future studies in field. Bouckaert and Davis (1998) [15] used an acoustic doppler velocimeter (ADV) [16] to perform in situ measurements and collect 3D data of velocities, $\tau$, and turbulence, while Gibbins et al. (2010, 2007) [17,18] used a portable flume for field measurements allowing manipulation of the water surface level and flow velocity for the investigation of how these variables change $\tau$ at the riverbed. In Reference [17], they showed that when $\tau$ is over 0.9 Pa (=9 dynes cm$^{-2}$), the rate of loss of animals increases considerably.

Measurement of $\tau$ at or near a wall can be very tricky [19] dependent on the flow conditions, but for certain cases, rather simple relationships exist. To exemplify, for developed flow in channels and pipes, $\tau = f(y)$ is simply given by a linear relationship for both laminar and turbulent flow according to:

$$\tau = Cy$$  \hspace{1cm} (1)  

where $C$ is a constant and $y$ the coordinate perpendicular to the wall and starting in the middle of the channel or the pipe [20] (Pope, Chapter 7). For non-developed flows, the shear stress is no longer constant as, for instance, shown for boundary layer flows in Reference [20] (Pope, Chapter 7). For such cases, measurements have been performed with different methods often with a focus on the wall shear stress [21–23] but also considering $\tau$ within the fluid [24,25]. Considering all these available works, the aim of this work is to reveal the flow conditions around the simplified arrangement of stones in order
to identify livable areas for benthic fauna by measuring the wall shear stress. This investigation is thus a complement to studies done in field with benthic fauna.

2. Experimental Setup

2.1. Water Flume

The experiments were conducted in a water flume with a smooth bottom and a length of 7.5 m and a cross-section of 0.295 m × 0.310 m. The steel base of the flume is flanked by two sets of glass planes. A honeycomb and a steel net were placed at the inlet of the water channel to obtain a uniform velocity distribution through the channel. The thickness of the honeycomb is 75 mm, and the diameter of the holes is 7.6 mm. The steel net used is made of a wire having a thickness of 0.8 mm forming 2.5 mm × 2.5 mm square holes. Water was pumped through the channel from a reservoir tank placed at the outlet that has a water storage capacity of 2 m³, and water is re-circulated back to the reservoir tank from the flume. A submersible pump controlled the flow rate, and the mean velocity in the channel was derived running PIV measurements on a channel without objects for several times as well as measured with a Coriolis flow meter. The temperature of the water was controlled to 20 °C using an automatic cooling arrangement. This is essential since variation in water temperature changes its viscosity and refractive index properties. Changes in water temperature may also lead to a displacement of the laser sheet and the plane of focus of the camera.

The water depth in the channel was maintained at 180 mm ± 1 mm for all measurement carried out. In order to minimize the reflections from the bottom of the water channel, a black-colored 2 mm thick Lexan plate with a width of 295 mm and length of 1500 mm was attached to the bottom. The edge of the plate was put at a distance of 3290 mm from the channel inlet, which is a distance judged sufficient to provide a steadily developed velocity profile in the area of interest. A schematic arrangement of the experimental set-up is presented in Figure 1.

![Figure 1. Schematic arrangement of the experimental set-up.](image)

2.2. Arrangement of Half-Cylinders

To model embedded stones in a riverbed, half-cylinders were placed on the bottom of the water flume, as mentioned previously. The half-cylinders with a diameter of 100 mm and 200 mm were hollow polymethyl methacrylate (PMMA) with the same thickness, 3 mm and spanned the full width of the channel in order to reduce 3D effects. The shape of the half-cylinders was maintained by attaching a plate with the same length as the half-cylinder and a width corresponding to the inner diameter. Heavy weights were placed into the hollow regions formed by the half-cylinders in order
to inhibit the arrangement from moving. To prevent water from seeping through the contact area between the bottom plate and the half-cylinders, silicon was used to seal the bottom edges of the half-cylinders. Furthermore, in order to avoid reflections from the half-cylinders, their surface was painted black. The half-cylinders were placed in two configurations according to big–small–big–small (BsBs) and small–big–small–big (sBsB), respectively; see Figure 2.

![Half-cylinder arrangements.](image)

**Figure 2.** Half-cylinder arrangements.

### 2.3. Experimental Technique (PIV)

PIV is a method to visualize and measure fluid flows in a two-dimensional plane \([10,26–28]\). A typical PIV setup consists of a light source which is usually a laser that illuminates the actual flow region of interest, forming a thin light sheet as shown in Figure 3. By seeding the fluid with small and neutral buoyant particles, the fluid motion can be measured as the particles pass the light sheet, being photographed by a high-speed camera. Each set of recordings consists of a number of double frame images that are divided into small regions called interrogation windows. Here, cross-correlation based on fast Fourier transform (FFT) is performed between the respective interrogation window in each frame resulting in a velocity vector field of the entire measured plane. Each vector represents the statistical mean velocity for the actual interrogation window \([29]\) (Raffel et al., 2007). Generally, the tracer particles should not move more than a quarter of the interrogation window width in order to have an optimum correlation scheme \([30]\) (Keane and Adrian, 1990).

![PIV measurement setup.](image)

**Figure 3.** PIV measurement setup consisting of a double-pulsed laser, imaging optics forming the laser sheet, and camera for recording.

The PIV system used in the present study is a commercially available system from Dantec Dynamics, consisting of a double-pulsed Nd:YAG L PIV laser from Litron having a maximum repetition rate of 100 Hz, and a FlowSense EO Camera with a spatial resolution of \(1280 \times 1024\) pixels per frame. The laser is mounted on a maneuverable traverse, allowing the laser sheet and camera to shift position 600 mm in the x, y, and z-direction, respectively. However, the camera was manually rotated in
both directions to obtain the PIV results in the normal direction to the curved surface, which was done using the trial and error method, enabling preview of DynamicStudio data acquisition software [31]. For the evaluation of $\tau$, the field of view (FOV) was set to $16 \times 16$ mm$^2$, being the smallest possible FOV for the experimental setup where a Nikon micro NIKKOR 200 1:4D lens was used. In order to disclose flow features on a larger scale, an additional set of measurements were carried out with a FOV of $120 \times 120$ mm$^2$ now using a Nikon NIKKOR 24 1:2.8D lens. Since pulsed light was applied in all these PIV measurements, the shutter speed of the camera is irrelevant.

The seeding particles used in the present study are non-fluorescent hollow glass spheres from Dantec Dynamics A/S, having a diameter of 6 microns and a density allowing them to follow the motion of the flow [29] (Raffel et al., 2007).

A sample raw PIV image at point 5 of BsBs for $U_\infty = 0.035$ before the interrogation process (raw PIV image) is shown in Figure 4 along with its interrogation processed vector field where the field of view (FOV) was $16 \times 16$ mm$^2$.

Figure 4. Particle image velocimetry (PIV) image at point 5 of BsBs for $U_\infty = 0.035$: (a) Raw PIV image, (b) processed vector field.

2.4. Experimental Scenarios

The traverse used to maneuver the camera has a total working range of 0.6 m; considering this and the camera field of view, the full working range is $\approx 0.62$ m. Hence, it is possible to do PIV measurements of the full geometry for both configurations.

Two free stream velocities were used for both arrangements, 0.035 m/s and 0.155 m/s; this corresponds to channel Reynolds numbers, Re, 3170 and 14,030, based on the hydraulic diameter of the channel, large cylinder Re 1950, 8650 based on the hydraulic radius of the large cylinder and channel Froude numbers, Fr, 0.026, 0.117, which mean that the flow for both cases is subcritical. The actual water level was kept constant at 0.18 m for all measurements avoiding disturbances, i.e., hydraulic jumps, on the free surface and also with respect to the volume of the tank. The laser sheet is applied from the top of the channel, and any disturbances on the free surface will have a negative effect on the quality of the laser sheet and, hence, the quality of the PIV measurements. This was minimized using a glass sheet over the free surface.
2.5. Error Analysis or Repeatability Test

Errors are mainly connected to the PIV measurements. Since PIV is a statistical method, the results are dependent on the sampling size and, generally, a large number of pictures generate results that are more accurate. For the present measurements, the sampling size was set to 1000 pictures, which is the maximum number for the PIV equipment used, and this sampling time was approximately 100 s. A repeatability test was conducted at four different times to find the differences in results at points where flow conforms with logarithmic velocity profiles. The largest difference (18%) was found close to the wall, and the error rapidly decreased when moving more than 1 mm away from the wall, and the smallest difference (0.9%) was found 5 mm away from the wall. The average difference between these repeated results was approximately 2%. The reason for the largest difference close to the wall may be traced to the uncertainty of the wall position and velocity fluctuations. Other errors, such as those generated by the measurements of flow rate and temperature and computations of averaged velocity, are assumed to be smaller. Further, the relatively low PIV Sampling rate (10 Hz) may introduce some errors, especially for the higher Re. These errors are still judged to be neglectable due to the long sampling time and since the dynamics of the flow is only studied for the lowest Re. It should also be noted that the velocity component in the z-direction is not measured. Neglecting this component, as done in this study, may, for instance, imply that the shear rate is underestimated. Additional errors also appear when the shear rate is derived, see Chapter 3.1.

3. Results and Discussion

3.1. Shear Stress Analysis

The wall shear stress at the cylinder boundaries, \(\tau_w\), is defined as:

\[
\tau_w = \mu \left. \frac{du}{dy} \right|_{y=0}
\]  

where \(\mu\) is the dynamic viscosity of the fluid and \(\frac{du}{dy}\) is the velocity gradient at the boundary.

Direct measurements of \(\tau_w\) require accurate measurements of velocities inside the viscous sublayer, very close to the wall. This is not always possible, and one common technique is instead to determine the shear velocity \(u^*\), defined as \(\tau_w = \rho u^*^2\), from the velocity profiles outside of the viscous sublayer [32–35]. For fully developed turbulent flows in pipes and channels, the dimensionless velocity profile can be described with the law of the wall, commonly expressed as:

\[
u^+ = y^+ \quad \text{for} \quad y^+ < 5
\]  

\[
u^+ = \frac{1}{\kappa} \ln \left( \frac{y}{y_0} \right) \quad \text{for} \quad y^+ > 30
\]

where \(u^+ = u / u^*\), \(y^+\) is the dimensionless distance from the wall defined as \(y^+ = y u^* / \nu\), \(\kappa\) is von Karman’s constant which is 0.41, and \(y_0\) is the roughness height [36,37], which is set to 0.05 mm [33], which corresponds to the roughness height of plastic material. By assuming that the boundary layer on the first half of the most upstream cylinder has a similar velocity distribution, it is possible to calculate the friction velocity from the measured mean velocity in the logarithmic layer and the logarithms of \(y\) and solve for \(u^*\) [38]. By using this procedure, \(\tau_w\) on the surfaces of the first half of the first cylinder for both cylindrical arrangements and \(U_\infty = 0.035\) m/s is plotted, see Figure 5 and the curve denoted Law of Wall. KX Whipple [39,40] described the regression process for this method to derive wall shear stress in detail. Since the flow can only be treated as fully developed in the beginning of the arrangements, the wall shear stress from the regression method was only calculated at five (sBsB) and six points (BsBs) on the first half of the first cylinder. The wall shear stress was also derived directly from the velocity gradient at 0.15, 0.25, 0.5, 1, 2, 3, and 5 mm distance from the wall at the same points,
assuming a linear relationship according to Equation (2), see Figure 5. The differences in computed wall shear stress at 0.15 mm and 0.25 mm are small, only about 2.1% in average, and hence, the velocity profiles are close to linear up to 0.25 mm, see Figure 6, which shows the velocity profile just before the midpoint of the first big cylinder for the BsBs case with \( U_\infty = 0.035 \) m/s. At larger distances, the computed \( \tau_w \) becomes smaller, since the distance from the wall is in the logarithmic layer and the assumption of a linear profile fails. Therefore, \( \tau_w \) was derived based on the velocity at a distance of 0.25 mm from the wall assuming a linear velocity profile up to this point. A comparison between this approach and the theoretical curve for a fully developed logarithmic velocity profile shows that the latter frequently used approach (i.e., [30–32]) gives a fair approximation, but as shown in Figure 5, there are some differences due to the complex geometry resulting in a non-developed flow. Hence, if possible, the shear stress should be derived from measurements of velocity very close to the bottom assuming a linear relationship up to the point of measurement. In addition, Figure 6 shows the velocity profile close to the wall at point 3 (3rd point in the Figure 5a from 0 x-coordinate downstream distance) for the case of BsBs for \( U_\infty = 0.035 \) m/s in scaled units, and it can be seen that the same regions that are typical for a “law of the wall” boundary layer can be identified at this point.

### 3.2. Time-Averaged Streamlines and Vector Fields

Before presenting the results of the shear stress at the wall, time-averaged velocity fields at certain areas will be presented. Figures 7–10 show the streamlines and vector fields for both the BsBs and sBsB
cases at different locations along the half-cylinder configuration for the two different mean free stream velocities: $U_{\infty} = 0.035 \text{ m/s}$ and $U_{\infty} = 0.155 \text{ m/s}$ for each case. Main flow direction is from left to right, and notice that Figure 7a, Figure 8a, Figure 9a, and Figure 10a show the area where streamlines and vector fields were captured with PIV.

![Streamline and vector fields for BsBs and $U_{\infty} = 0.035 \text{ m/s}$](image)

**Figure 7.** Streamline and vector fields for BsBs and $U_{\infty} = 0.035 \text{ m/s}$: (a) Area of interest (b) streamlines (c) vector fields.

Figure 9. Cont.
Figure 9. Streamline and vector fields for $s_{B}B$ and $U_{\infty} = 0.035$ m/s: (a) Area of interest (b) streamlines (c) vector fields.

Figure 10. Cont.
when the flow is not detached from the cylinders. However, in the recirculation zones, the $\tau_w$ again in the next recirculation zone. The largest midpoint of the second large cylinder as the flow starts being regular there, but the it continues to vary in the recirculation zone. The ratios of $\tau_w$ maximum of $\tau_ww$ is at the second big cylinder for the low Re, while it is at the first big cylinder for the high Re, see Figure 11b. Otherwise, $\tau_w$ becomes small. For the higher Re, $\tau_w$ increases considerably, see Figure 11c.

For the sBsB cases, $\tau_w$ behaves in a similar way. To exemplify, for both arrangements, the maximum of $\tau_w$ is at the second big cylinder for the low Re, while it is at the first big cylinder for the high Re, see Figures 11 and 12. This may be an inertia effect, meaning that the flow is to a larger extent deflected away from the arrangement at the higher Re.

In order to quantify the effect of increasing the free stream velocity from $U_\infty = 0.035$ m/s to $U_\infty = 0.155$ m/s, the absolute value of ratios when dividing $\tau_w$ for the larger velocity with that of the lower is shown in Figures 11d and 12d. The ratio in $U_\infty = 4.4$ is plotted in the figures for comparison. It is seen that these ratios of $\tau_w$ are close to 4.4 until half of the first big cylinder for the BsBs case, Figure 11d. Then it increases in value in the first recirculation zone where the flow speed is low, and it continues to vary in the recirculation zone. The ratios of $\tau_w$ become close to 4.4 again around the midpoint of the second large cylinder as the flow starts being regular there, but the $\tau_w$ ratio fluctuates again in the next recirculation zone. The largest $\tau_w$ ratio is found where flows are low or reverse. The $\tau_w$ ratio for sBsB, as shown in Figure 12d, behaves in a similar manner, and it can be concluded that the $\tau_w$ ratio between the different flow rates is directly dependent on the free stream velocity ratio when the flow is not detached from the cylinders. However, in the recirculation zones, the $\tau_w$ ratio can be influenced to a larger extent. This is nearly always due to the fact that both $\tau_w$ are small. There is A main characteristic for all cases is a high-speed flow field on the top of the cylinders. This is shown by the streamlines as well as the red arrows in the velocity field. For the higher Re, this flow moves a little bit deeper into the spaces between the cylinders. Another main feature is the recirculation zones, vortices, formed between the cylinders. For both cases, these zones change in shape as Re increases. It can also be noted that the velocity of these circulations is relatively low.

3.3. Shear Stress

The distributions of $\tau_w$ over the semi-circular cylinders are shown in Figures 11 and 12, where Figures 11a and 12a show how the cylinders are arranged and Figure 11b,c and Figure 12b,c show $\tau_w$ as a function of position for the two free stream velocities, respectively.

It is seen from Figure 11b that, for the BsBs case, $\tau_w$ gradually increases as the flow is directed upwards at the first cylinder until its mid-point where $\tau_w$ is at its maximum. The rapid decrease that follows indicates that the flow detaches from the cylinder, forming a rather large area with a low $\tau_w$ being in agreement with Figure 7. The negative extreme value in Figure 11b that follows is a result of the recirculation zone shown in Figure 7. The second positive extreme value is due to the fact that the high-speed flow field attaches to the larger cylinder. This field detaches again and does not reach down to the smaller cylinder that follows, and since the recirculation that forms in the beginning of the last cylinder is not strong, $\tau_w$ becomes small. For the higher Re, $\tau_w$ increases considerably, see Figure 11c.

For the sBsB cases, $\tau_w$ behaves in a similar way. To exemplify, for both arrangements, the maximum of $\tau_w$ is at the second big cylinder for the low Re, while it is at the first big cylinder for the high Re, see Figures 11 and 12. This may be an inertia effect, meaning that the flow is to a larger extent deflected away from the arrangement at the higher Re.

In order to quantify the effect of increasing the free stream velocity from $U_\infty = 0.035$ m/s to $U_\infty = 0.155$ m/s, the absolute value of ratios when dividing $\tau_w$ for the larger velocity with that of the lower is shown in Figures 11d and 12d. The ratio in $U_\infty = 4.4$ is plotted in the figures for comparison. It is seen that these ratios of $\tau_w$ are close to 4.4 until half of the first big cylinder for the BsBs case, Figure 11d. Then it increases in value in the first recirculation zone where the flow speed is low, and it continues to vary in the recirculation zone. The ratios of $\tau_w$ become close to 4.4 again around the midpoint of the second large cylinder as the flow starts being regular there, but the $\tau_w$ ratio fluctuates again in the next recirculation zone. The largest $\tau_w$ ratio is found where flows are low or reverse. The $\tau_w$ ratio for sBsB, as shown in Figure 12d, behaves in a similar manner, and it can be concluded that the $\tau_w$ ratio between the different flow rates is directly dependent on the free stream velocity ratio when the flow is not detached from the cylinders. However, in the recirculation zones, the $\tau_w$ ratio can be influenced to a larger extent. This is nearly always due to the fact that both $\tau_w$ are small. There is
also a small error introduced in the evaluation. Measuring exactly at few points for two flow cases was very difficult to maintain; there could therefore be small changes in the position of the measuring points contributing to the extreme $\tau_w$ ratio in a few points.

Figure 12. Shear stress distribution for sBsB.

Up until now, focus has been on mean values of $\tau_w$. Due to phenomena like turbulence and shedding, $\tau_w$ will be time-dependent, see Figure 13, being time-resolved $\tau_w$ for three points. As seen, the time-dependent appearance of $\tau_w$ is different for the three points. Most characteristic are the peaks for point B located in the recirculation zone. Comparing these peaks to those obtained for points A and C reveals that the peaks for point B are based on single values, while those obtained for points A and C are built from several points.
Until now, focus has been on mean values of $\tau_w$. Due to phenomena like turbulence and shedding, $\tau_w$ will be time-dependent, see Figure 13, being time-resolved $\tau_w$ for three points. As seen, the time-dependent appearance of $\tau_w$ is different for the three points. Most characteristic are the peaks for point B located in the recirculation zone. Comparing these peaks to those obtained for points A and C reveals that the peaks for point B are based on single values, while those obtained for points A and C are built from several points.

From Table 1, it is seen that ratios between $\tau_{w\text{max}}$ and $\tau_{w\text{mean}}$ and $\tau_{w\text{min}}$ and $\tau_{w\text{mean}}$ are significantly higher for point B compared to other points A and C. This is because this is the recirculation area where flow speed is mostly low, but sudden large fluctuation leads to $\tau_w$ becoming high. Thus, even if flow rate is constant, there can be sudden changes in $\tau_w$ in the low velocity areas. This is obviously important for the benthic fauna. The standard deviation (SD) of $\tau_w$ at point A is significantly low compared to the other two points, and the ratio between $SD\tau_w$ and $\tau_{w\text{mean}}$ is also smaller than that of the other two points B and C if the values are absolute. As a low standard deviation means that most measured values are very close to the mean, while high standard deviation means that measured values are spread out from mean [41], measured values at point A are very close to mean but measure values at further downward points increase gradually as the flow field is complex where recirculation occurs.

3.4. Critical Shear Stress

Livable areas of species are here defined as the areas in the bottom of the river where a certain species is able to maintain their position in the riverbed at a specific flow rate. By assuming that the
wall shear stress is the restricting parameter, the livable area for a species can be calculated as the area where the absolute value of $\tau_w$ is below the species critical value $\tau_c$. The ratio of livable area in this experimental set-up for different values of $\tau_c$ (which could be related to different species) is plotted in Figure 14 for the two mean free stream velocities. Absolute values of $\tau_w$ are used, since the resistance of the species to $\tau_w$ is independent on direction. The trend is the same for all experimental scenarios where the percentage of the bottom surface being livable increases fastest with $\tau_c$ in the beginning for both mean free stream velocities. An interesting observation is that the influence of arrangement of the half-cylinders (BsBs or sBsB) is small, with a slight trend that the BsBs arrangement creates a larger percentage livable area. It is also obvious that the % livable area is dependent on the free stream velocity. To exemplify, for species with $\tau_c = 0.1$ Pa, the percentage livable area for the BsBs arrangement is 100% and about 60% for $U_\infty = 0.035$ m/s and $U_\infty = 0.155$ m/s, respectively.

4. Conclusions

In this paper, the flow around half-cylinders at the bottom of an open channel was measured using particle image velocimetry (PIV). The main objective was in addition to the main flow characteristics near the bottom, to investigate the distribution of shear stress along the bottom objects. The key question addressed was how shear stress changes in the livable area on the half-cylinder configuration. It was shown that the flow pattern is dominated by vortical structures between the half-cylinders and on the leading and trailing sides of the cylinder sets. It was shown that the regression method that calculates wall shear stress from the measured velocities in the logarithmic boundary layer predicts the correct order of magnitude but differs for measurement points along the first cylinder in the investigated simplified stone configuration. This indicates that direct measurements of near wall velocity gradients are necessary to accurately calculate the wall shear stress for more complex geometries. Considering a critical shear stress, it is shown that the trend is close to identical for all experimental scenarios with a percentage of the bottom surface being livable where critical shear stress varies significantly for different mean free stream velocities. The changes in wall shear stress as a function of arrangement, free stream velocity, and time implies habitat heterogeneity, allowing benthic invertebrates with different shear stress tolerance to exist when the bottom consists of differently sized stones [5], which can be an addition to available research work. The variation in time also enables adequate nutrition and oxygen [4].
Future work may consider additional measurements possible with stereoscopic [42] or tomographic PIV [43] in lab to capture 3D effects when, for instance, introducing artificial structures [9] (Jeffries and Mills, 1990) and measurement in field.

Author Contributions: S.M.S.B.A. and T.S.L. conceived and designed the experiments; S.M.S.B.A. performed the experiments and analyzed the data; A.G.A. also contributed in a little part of the analysis and manuscript writing; S.M.S.B.A. wrote the paper; all authors read and approved the final manuscript.

Funding: This work has been funded by the collaboration initiative StandUp for Energy and ELFORSK (now ENERGIFORSK). The research program is a part of the Swedish government’s commitment to high-quality research in areas of strategic importance.

Conflicts of Interest: The authors declare no conflict of interest.
